MALIGNANT TUMOR OF THE UPPER JAW AND CYSTIC TUMOR OF THE NECK.

A Clinical Lecture, delivered at the City Hospital, Charleston, S. C.

By R. A. KINLOCH, M.D.,
PROFESSOR OF SURGERY IN THE MEDICAL COLLEGE OF THE STATE OF SOUTH CAROLINA, CHARLESTON, S. C.

(Reported by John L. Dawson, Jr.)

Gentlemen: I bring before you this morning two cases of much interest. One, this middle-aged colored man, with a tumor of the upper jaw; the other, this young white man with a tumor of the neck, sent to me as a probable case of "aneurism of the carotid."

The first patient, I saw for the first time just before coming into this room, having been stopped on my way here by one of my colleagues, and asked to give an opinion as to the propriety of an operation for the relief of the sufferer. This man comes here from a distant part of the State, and is willing to submit to any surgical operation that may be deemed advisable.

You notice the enlargement of the upper jaw on the right side, and see the two fistulous openings in the soft parts discharging a thin pus. The soft parts of the cheek, integument and all, are fixed to the bone, and cannot be made to glide over it, as is usual in the healthy condition. Let us look into the mouth, first, I see that the teeth of the jaw on this side are gone. The man says that these loosened and dropped out one by one. This is ever a suspicious circumstance in connection with tumors or diseases of the jaws, and indicates serious if not malignant disease. Such disease often begins in one of the alveolar cavities, but may start elsewhere, as between the outer and inner lamina of the bone, or in the antrum, and finally involve the alveolar border as well.

In this case the mass of bone is assuredly implicated; it is no simple tumor of the soft parts. Upon further examination, it is seen that the bone expansion is more marked towards the cavity of the mouth, and that the tissues composing the roof of the mouth are thoroughly involved. The mucous membrane of this region is granular, thickened, and ulcerated. Pressing the bone, or the tumor, between the fingers that I have within the mouth and those upon the outer side resting upon the cheek, I note that the force is communicated from within to the outer side, or from without to within. The solid bony tissue has, for the most part, disappeared, or been substituted by soft, diseased tissue which makes up the bulk of the neoplasm, or new growth. The bone has literally been fed upon and thus consumed. At points, however, there are portions of bone remaining which crack under pressure. Trace the growth backward, with the finger in the mouth, and we find it goes beyond the palate bone toward the pharynx and the base of the skull. We realize that we have to deal with an extensive and a most destructive growth, involving alike bone and soft parts that are connected more or less intimately with vital portions of the organism. Wherever it began, it has been long infiltrating adjacent structures, and promises still further to extend its ravages by a forced, unnatural union with the elements of all the tissues. Secondary and inflammatory changes also further the processes of development of the original growth. Such are what we may in part call malignant features of the disease. At present we can perceive no general infection, but such must soon follow, and the vital fabric must finally yield to the fearful ravages that, I fear, neither surgery nor medicine can arrest. Need I name to you this disease? Practically, we can call it a malignant tumor of the jaw. Perhaps it is entitled to be called cancer or carcinoma. Perhaps, and I think more likely, for reasons which I cannot now, for want of time, fully explain, it may be regarded as a sarcoma. Clinically, there is but little difference between some disease differently named, and, in the case before us, with the progress that has been made, and the destructive changes that have resulted, a pathological argument or demonstration will not very much aid the surgery for the occasion. I hope to explain this to you more fully hereafter.

We often have sarcomata of the jaws amenable to treatment. But in regard to this case of disease, I hesitate not to tell you that in my belief, surgery is powerless. I cannot sanction an operation here. By no operation, however bold, or however skilful, could we expect to insure the removal of all the infiltrated morbid elements. A removal of all apparently diseased structures is not sufficient in such cases. You must go far and wide of the disease, and seldom do we know certainly when we have gone far enough. Operations in such cases as this bring only discredit upon surgery. There may be a chance for bold operating, for an exhibition of skill as a dissector. To be able to say how extensive have been incisions, how numerous the vessels divided and tied, how vital the parts exposed, seems, from reports of cases we see in journals, to be the aim and satisfaction of some operators. These men do not represent surgery. I beg you not to be captivated by their examples or teaching. I will then, for reasons that you must appreciate, advise that this poor man be left to his fate, with the simple comfort that can come of judicious palliative treatment. We may assuage his suffering; we cannot save, and can hardly prolong his life.

This other case is a very different one. You see we have here a tumor of the right side of the neck, below the larynx, and over the course of the carotid artery. The case was sent to me as probably one of *carotid aneurism* by a medical friend in the interior of the State. The tumor is spherical, as large as an orange, tense, and, as I think, fluctuating to the touch. It is said to have been developing for two years, and not to have given pain, *mark you*, until three weeks ago, when there began a "dull aching," which has continued up to this time. My medical friend who saw the case in its incipiency thought there was then an obscure pulsation in the swelling.

The position of the tumor is one where aneurism is at times found. We may have many other forms of morbid growth in the same site. Glandular tumors in this region are common. Fibroid, or fibro-cellular, tumors also occur here, and at times it is possible that such growths may receive a pulsatory movement from their proximity to the main artery of the neck. Besides these we have, more rarely, cystic or fluid tumors in this location. We hear such, at times, called "hydroceles" of the neck.

The origin of such cysts is obscure. They may begin *de novo*—there being no natural cyst to develop into a tumor—in the loose connective tissue of the region and grow to an enormous size, the tumor finally hanging down over the sternum. The growth before us, from its shape, elasticity and fluctuating feel, I decide to be a liquid and not a solid tumor. The most careful examination fails to connect with it any pulsation. Pressure upon the carotid at the sterno-clavicular junction in no way affects the size of the swelling. It is therefore not an aneurism. I exclude the solid growths at times met with here, and I think I can also exclude the idea of malignancy. We have, in other words, to deal neither with a cancer nor a sarcoma.

The appearance of the patient, the time the tumor has been growing, the non-infiltrating character of the disease, all sustain this conclusion.

Cystic or fluid tumors, however, I must not forget to tell you, are not always simple or benign. There may be within, connected with the sack, a cancerous or a sarcomatous element. But I will not wander so far as to consider such a matter now.

One point more: an abscess, as you know, is a kind of fluid tumor, and we must not fail to consider the question of abscess in connection with the case before us. The growth of two years, and the absence of all signs of acute action at present might permit us to exclude abscess as we have done certain kinds of tumors. Chronic abscesses, however, often exist a long time without appreciable inflammatory symptoms. Such are, however, seldom found precisely in this region without being connected with glandular or with spinal disease. There are no evidences of such connection with the tumor before us. If originally there was a glandular swelling, this has disappeared by disintegration. But to consider one feature in the case before alluded to; there has been *pain for several weeks*, and since the commencement of this acute symptom, the tumor has become more tense, or, as the patient thinks, "has grown more rapidly." Without an external trace of inflammation, pus may form within a cyst. You see, gentlemen, that the question of diagnosis, although not certainly fixed, is narrowed down very decidedly. I come to the question of the *contents* of the cyst, or the fluid tumor. Fortunately, we have a means of absolutely determining this matter. We can explore or aspirate almost any morbid growth, and with but little risk to the patient. We can abstract the contents of a fluid tumor and examine the material to render certain a diagnosis. This is what I will now do before you.

This little instrument, the hypodermic syringe, answers the purpose very well in such a case. I plunge the delicate needle, or trocar, into the centre of the swelling, as you see, and then retract the piston. The glass barrel of the little syringe slowly fills with a turbid, viscid liquid as I proceed. This is sufficient. I withdraw the needle, and finish the little operation. To be certain, we might subject the liquid to microscopical examination, but this is scarcely necessary for my present purpose. The fluid is evidently sero-purulent in character. The pus is in small quantity. We have no simple abscess of either the acute or chronic form. The fluid withdrawn substantiates this opinion. What is next to be done to relieve the patient? This is at last the most practical, because the vital question; we must empty the cyst, which I will now do by a free incision, and then make use of means for destroying its secreting surface, so as to make it fill up and heal like an abscess. You see how my free incision permits the escape of pus, together with the viscid glairy matter, and some little blood. We will now wash out the cavity with a weak iodine solution (℥j of the tinct. of iodine to ℥vj of water), then put in a drainage-tube, and cover the neck with a layer or two of borated cotton, secured in place by a bandage. The object of the iodine is twofold: it is antiseptic and also a good stimulant to rouse up the action of the cyst wall and effectually change the character of the secreting surface. We will expect to keep the cavity aseptic, by repeated injections of iodine solution, and hope that the boy will recover.

I cannot explain to you the origin of this disease; my finger passed to the bottom of the cavity, failed to discover any trace of a solid growth, glandular or otherwise. The sac evidently extends deep into the tissues of the neck and is in close relation to the important vessels.

[This patient made a good recovery, and returned home three weeks after the operation.]

ORIGINAL ARTICLES.

A CASE OF MULTIPLE FRACTURE.

BY J. HENRY C. SIMES, M.D.,
ASSISTANT SURGEON TO THE EPISCOPAL HOSPITAL, PHILADELPHIA.

THE following case is reported as being one of unusual occurrence, and also on account of certain peculiarities, which may be stated as follows: First, the number and gravity of the injuries; second, the course of treatment adopted; and, third, the result.

In regard to the first, the multiplicity of the fractures, it is very rare to meet with this condition, as a result of traumatism not complicated with some constitutional diathesis. Most of the cases reported by authors have occurred in patients who, at the time of accident, were suffering from cancer, syphilis, rickets, gout, or other constitutional disease, and which are known to be predisposing causes; but in the case here related, there were no existing cause or causes as far as could be ascertained. The fractures were the result of uncomplicated traumatism.

The second point—the treatment—is seen to be one of conservative surgery, and also one in which antiseptics were employed as auxiliaries. That the latter were the principal and only reason for the successful termination I am not prepared to decide; but it does seem to me that the result was, in a measure, determined by this method of treatment. When the course of similar injuries, treated by a non-antiseptic method, is contrasted with this case, it would appear that it is an exception to the general rule, and it is not unreasonable to suppose that the possibility of the favorable termination was somewhat influenced by the antiseptic treatment.

Finally, the result—this was unexpectedly very satisfactory, and may, I think, be attributed in part to the patient herself, who was of a decidedly phlegmatic temperament, and never lost hope, but, from the beginning, was firmly determined upon recovery; in part, to the method of treatment adopted; and, in part, to the unremitting care and attention of Dr. Edward S. McIlvaine, the resident of the surgical ward, under whose charge the patient was placed.

Louisa M., aged 29 years, was admitted into the hospital on the evening of September 19, 1882. Two hours previous to her admittance, she had jumped from the third-story window of her dwelling. I saw her early the following morning, and an examination of her injuries was made. There were two simple fractures of the inferior maxillary bone—one situated at the ramus, the other at the symphysis: a simple oblique fracture at the middle third of the left femur; a compound comminuted fracture at the lower fourth of the right femur; contusions of the skin over both knees and on the arms; the right knee-joint was much swollen, the effusion being within the capsule of the joint, and very distinctly floated the patella. On account of this swelling of the joint, it was difficult to ascertain the exact condition of the bones constituting it, but it was thought that there was an intercondyloid fracture of the femur communicating with the cavity of the joint. The wound of the thigh was about one and a half inches long, located at the outer side of the thigh, on a line and two inches above the outer condyle of the femur. Upon passing the finger into this wound, it came in contact with the shattered bone, a fragment of which was found separated from the shaft, and lying in the lacerated muscular tissue.

The general condition of the woman was remarkably favorable; there had been very slight, if any, shock; the temperature was 100° F.; the pulse about normal; she had complained but little of pain; even while undergoing the examination necessary to determine the extent of her injuries, she apparently suffered very little, and certainly did not realize the gravity of her condition. From my examination of the injuries, and the state of the patient, the following treatment was decided upon:

The fractures of the inferior maxillary bone were in very good position, and a Barton's head-bandage was applied, which admirably fulfilled very indication for the treatment of this injury.

The simple fracture of the left femur was dressed by extension, and a large sand-bag placed at the outside of the limb, extending from above the crest of the ilium to below the foot. The extension was obtained by means of two broad strips of adhesive plaster—one placed on the external and one on the internal surface of the limb—they were secured by transverse strips, and reached from the upper extremity of the lower fragment of the fractured femur to two inches below the foot, over which was applied a spiral-reverse roller: a piece of splint board, wide enough to prevent pressure upon the malleoli by the adhesive plaster, was attached to the lower end of the strips of plaster. A cord having a weight attached to it was fastened to the board, and passed over a pulley at the end of the bed. The counter-extension was obtained by elevating the foot of the bed.

The treatment of the injury to the right limb was the most difficult to decide. There was a compound comminuted fracture of the shaft of the femur, and also, possibly, an intercondyloid fracture communicating with the knee-joint; effusion into the joint cavity was undoubtedly present. A careful examination of the circulation and temperature of the leg showed nothing abnormal. The general condition of the patient, as previously mentioned, was remarkably good, and, notwithstanding the great gravity of the injury, I thought, with unusual care and attention, an operation might be avoided, at least for the present, since, with her other injuries, an amputation would, in all probability, prove the straw too much.

The examination had shown that a portion of the fractured femur was detached and lying loosely in the muscles; this could only act as a source of irritation, and it was thought best to remove it. In order to do this, the wound was enlarged, under the carbolic spray, and the fragment of bone removed. The piece of bone, when removed, proved to be much larger than was anticipated: it measured three inches in length, and included about half the circumference of the femur. It was entirely denuded of periosteum, and from that portion of the shaft of the bone, just above where it begins to expand into the condyloid eminence. The wound was then thoroughly washed with a watery solution of carbolic acid, using a syringe to force the solution into all parts of the wound; a folded piece of lint, saturated with carbolized water, which covered the wound and upper surfaces of the thigh and knee-joint, was then applied. To prevent all motion, as far as possible, the limb was placed on pillows in a long fracture-box, which reached from the perineum to below the foot, the lower part being elevated to form an inclined plane. An irrigating apparatus was then arranged, so that the piece of lint, covering the thigh and wound, was kept constantly wet with the carbolized water. This completed the dressings, and the patient stated she felt as comfortable as possible under the circumstances; indeed she was soon asleep.

The day following I found the patient had developed no unfavorable symptom; she was in good spirits, and more resigned to her confined position. In consultation with my colleague, Dr. Nancrede, it was concluded advisable to let well enough alone, and, therefore, the same treatment was continued. On September the 19th, the third day after the accident, it was found necessary to make some change in the manner of applying the carbolized water. It was not possible, on account of the other injuries, so to arrange the irrigation, in order to prevent the water from passing under the patient's back, and being a constant source of annoyance to her. To avoid this difficulty, the irrigating apparatus was removed, and in its place the folded lint, covering the thigh and wound, was wet every fifteen or twenty minutes with the carbolized water.

The above treatment, without any change whatever, was continued for twenty days. During all this time there were no unfavorable symptoms; the effusion in the knee-joint gradually disappeared; no pus was discharged from the wound, nor were there any collections in the tissues around the injury. A very small amount of a lemon-colored fluid, just enough to stain the lint in immediate contact with the wound, was all the discharge ever observed. The pain at no time was so severe as to require anodynes; occasionally, at night, a small dose ot sulphate of morphia was administered to relieve restlessness. The appetite remained good—in fact, she complained of being hungry, not relishing the liquid diet necessitated by the fractures of the jaw.

My term of service at the hospital having expired, the patient was taken charge of by Dr.

Packard, and I have since ascertained that there was an uninterrupted course of improvement until she left the hospital on December 11, 1883. At the present time, seven months after receiving the injuries, she has so far recovered as to be able to perform her house duties, and to walk without pain or difficulty. A slight stiffness of the right knee-joint is the only remaining lesion of her injuries.

VLEMINCKX'S SOLUTION IN ACNE ROSACEA.

BY H. W. STELWAGON, M.D.,

PHYSICIAN TO THE PHILADELPHIA DISPENSARY FOR SKIN DISEASES; SERVICE FOR DISEASES OF THE SKIN, NORTHERN DISPENSARY; AND DEPARTMENT FOR DISEASES OF THE SKIN, HOWARD HOSPITAL.

THE condition known as acne rosacea, or rosacea, is so obstinate in its nature that in many instances almost every remedy is barren of any marked or permanent result. What will prove useful in a certain proportion of cases, will be of little avail, or even absolutely valueless, in others. The importance, then, of having at command a large choice of remedies is evident. Remedies are referred to here in the sense of local application only, as it is generally by such means alone that any good is obtained. Internal medication is rarely of advantage, and is seldom called for, except to correct faulty conditions in the general health that may be present. The use of Vleminckx's solution in this affection is not original with myself, as it has been, to my knowledge, so used by Dr. Duhring and Dr. Van Harlingen, as well as by other dermatologists. This application of it is, however, but little known to the general profession, and it is for the purpose of calling further attention to its value that the present communication is written.

The solution is made by adding one part of lime and two parts of sublimed sulphur, or flowers of sulphur, to twenty parts of water. This is boiled down to about twelve parts, cooled, and then filtered. The result is a dark, orange-yellow colored liquid, with a strong odor of sulphuretted hydrogen. This is to be diluted as circumstances require. A brief description of a few cases will illustrate its value and mode of application.

CASE I.—Albert B., a druggist, aged 19, applied at the Philadelphia Dispensary for Skin Diseases, January 2, 1882. The nose was erythematous, and, with the surrounding parts, presented a few acne pustules and numerous comedones. Health was fair, with occasional attacks of indigestion. He was ordered to make applications of hot water to the parts at bedtime, subsequently press out as many comedones as possible, and then apply for several minutes a lotion made up of one part of Vleminckx's solution to five of water. In addition, he was prescribed an aperient mixture to be used when required. He returned at intervals of ten days, and the proportion of Vleminckx's solution was gradually increased to one part to three. Improvement ensued from the start, and at the end of two months the patient was so well satisfied that he ceased his visits.

CASE II.—Morris F., peddler, aged 40, applied at Philadelphia Dispensary for Skin Diseases, February 2, 1882. Nose and immediate neighborhood and forehead near middle were markedly erythematous, and presented a number of small acne papules and pustules. About the nose the capillaries were enlarged. Had indulged some years previously in alcoholic excess, but during the past few years had been temperate. Disease had existed three years. General health good. An aperient was ordered to be used occasionally, and at bedtime to apply, for several minutes, a lotion of one part of Vleminckx's solution to four of water. Patient returned in three weeks somewhat improved. Strength of lotion was gradually increased to one part to three. From this time on, patient continued to improve steadily, without further increasing strength of wash. At each visit, the larger capillaries were incised. Last visit was made April 24, about three months after beginning treatment. Patient was well satisfied with the improvement in his appearance, and, although not absolutely well, failed to return.

CASE III.—Jane M., aged 36, domestic, presented herself for treatment at the service of the Northern Dispensary, March 11, 1882. Chin, nose, and middle of forehead dull red, and covered irregularly with acne pustules; enlarged capillaries about nose. Health was good, and the functions well performed, except that there were occasional attacks of indigestion. An aperient tonic mixture was ordered for the dyspeptic symptoms, and a lotion of one part of Vleminckx's solution to five of water, to be applied for several minutes every evening. Patient returned three weeks later, and condition had much improved; same was continued. At end of two weeks, patient again appeared, and marked improvement was noted. The acne had almost entirely disappeared, and the rosacea was less marked. The larger vessels were incised. Lotion was increased one part to four, and later, one to three. Improvement continued, and three months after her first visit, patient was completely rid of her trouble.

Examples such as are just cited, might be multiplied, as the disease is a rather common one at the dispensaries, and the record-books contain a number of such cases, showing the value of this remedy, and I may here add, also a proportion of failures. In some cases, it is necessary to gradually increase the strength of the lotion, even up to the pure solution. This is, however, rare. The strengths as given in the above cases are generally sufficient. At times it is well to intermit treatment for a few days, in order that the desquamation it usually causes may disappear. The milder strengths cause very little desquamation, and, in moderate cases, are sufficiently efficacious. Occasionally, especially in the more obstinate cases, the lotion may be advantageously made stronger. In most cases, the improvement would be more rapid were the lotion applied twice daily, night and morning. It is difficult, however, to get patients to make applications early in the day, on account of personal appearance. The severe forms of the disease, those in which hypertrophy is a marked feature, are comparatively rare, and as yet I have had no opportunity of testing the solution in such cases. It would probably be of little value, as the disease, when so advanced, is rarely benefited by any treatment, except those plans in which operative measures figure prominently.

Even in the moderate forms, some cases fail to respond to the application of the solution, and other treatment must be instituted, in order to secure improvement.

Vleminckx's solution is not, therefore, in any sense, a specific—far from it. It frequently fails and disappoints. Upon the whole, however, according to my experience, it is, for the milder forms of the affection, the most reliable single remedy.

MEDICAL PROGRESS.

Galvanism in Nervous Cephalalgia and Hemicrania.—Dr. Gasparini has successfully employed galvanism of the cervical sympathetic in cases of nervous headache and hemicrania. These cases, as a rule, present symptoms of indigestion, and in many cases malnutrition. After a short course of treatment the patients, in most of the cases, regained their digestive powers, nutrition was improved, and the head symptoms ceased.—*Gaz. degli Ospitali*, May 30, 1883.

Periodic Recurrent Paralysis of Ocular Muscles.—A remarkable case of paralysis of the ocular muscles, coming and going every month simultaneously with the appearance and disappearance of the catamenia, has been recorded by Von Hasner (*Centralblatt für klin. Med.*, No. 21). It occurred in a girl aged seventeen years, of good physique, who had suffered since her thirteenth year from ptosis of the left upper eyelid, which set in every month, lasted three days, and was accompanied at its commencement by headache and vomiting. Menstruation began at the age of fifteen years, when it was observed that this coincided with the monthly ptosis of the left eye. The author had the opportunity of seeing the patient at the onset of one of her periods, and then made out total palsy of the muscles of the left eye; the second day of the menstrual period witnessed a regression of the paralysis of the left eyelid, of the headache, and vomiting. With the cessation of the menses on the third day, a gradual restoration of the movements of the eye took place, the pupil remaining dilated a little while longer.—*Med. Times and Gaz.*, June 9, 1883.

Malarial Laryngitis.—Dr. E. Briand having seen certain cases of false croup of no other than malarial origin, concludes that: 1. There exists a form of laryngitis due to malaria, characterized by congestion of the larynx, giving rise, from a symptomatic point of view, to the functional signs of true croup. 2. This variety of laryngitis differs from laryngismus stridulus by the symptoms, course, and prognosis, and generally yields to treatment by sulphate of quinine. 3. It is not very rare in infants, and may be recognized by the fact that it is preceded or followed by malarial manifestations.—*Revue Méd. Franç. et Étrang.*, May 26, 1883.

The Internal Employment of Glycerine.—In a recent *thèse de Paris*, M. Tisne (*Journal de Thérapeutique*, April 25) gives an account of the results of the employment of glycerine by Drs. Jaccoud and Ferrand. The former prescribes it as a stimulant to the digestive organs in the non-febrile stage of phthisis, when for any reason cod-liver oil ceases to be tolerated. The following mixture is given daily in two or three doses: Glycerine, forty; and rum or cognac, ten grammes; with one drop of essence of mint. This aromatized alcoholized compound, of agreeable flavor, is well tolerated by the stomach, and even after long uninterrupted employment it causes neither satiety nor disgust. The addition of the rum or brandy has simply in view the modification of the insipid taste of the glycerine, and to assist its digestion. The amount of glycerine may be raised to fifty or sixty grammes, but only in persons who do not exhibit any sign of abnormal excitability of the heart or nervous system; and restlessness, unusual loquacity, obstinate insomnia, or an increase of temperature announce that the proper dose has been exceeded. Dr. Ferrand makes daily use of glycerine in his wards at the Laennec, and it is found to be readily absorbed, without producing any toxical effects. It diminishes constipation in almost all cases, and yet moderates diarrhœa when this is present; and under its use sleep becomes calmer. It has an evident effect on nutrition, its employment in most cases leading to an increase in weight after the first fortnight. In tuberculous cases it induces a considerable amendment in the functional manifestations of the disease, such as dyspnœa, cough, and sweating. The expectoration is the symptom which is least influenced. The local condition of the lung also remains stationary, and the physical signs undergo no change. The action of glycerine on the liver is exhibited by the increase of its size and by the more abundant flow of bile. With respect to its action on the kidneys, there are observed a more abundant diuresis and an absolute and relative increase of urea, the chlorides and phosphates eliminated by the urine. In affections of the genito-urinary organs, M. Tisne has found that under the use of glycerine the alkalescence of the urine seems to diminish, while purulence, when present, becomes considerably lessened.—*Medical Times and Gazette*, June 16, 1883.

Action of Mixed Vapor of Chloroform and Air.—Prof. Paul Bert has shown that ʒijss of chloroform vaporized in one quart of air will anæsthetize a dog; ʒvj of chloroform in a quart of air will kill the dog. Wishing to know if the same effects would be produced in case the experiment is continued for several hours, by a particular arrangement he was enabled to protract the experiment during ten consecutive hours. ʒss of chloroform vaporized in a quart of air produces no appreciable result; ʒj in one quart of air was respired without trouble, and with no diminution of sensibility, but there was a decrease of temperature amounting to four or five degrees.; ʒjss to ʒij in the same quantity of air produced great diminution of sensibility, but was only manifested after a considerable time; the temperature fell rapidly, and after seven hours of the experiment the animal died with a very low temperature.

The temperature was always lowered in proportion to the duration of the experiment. In some cases the temperature was lowered and death took place before anæsthesia was produced. In these cases, depression of the nervous system was not the cause of death. In whatever manner death is produced, the heart always beats to the end. Chloroform does not act, then, upon the heart. Chloroform should be given intermittingly, and animals which have sustained a loss of blood are much more sensible to it, and much more likely to die under it than otherwise; and the safest procedure is to cause anæsthesia rapidly, and then give in small and intermittent doses.—*Journ. de Méd. de Paris*, May 26, 1883.

Contagion of Measles.—Dr. A. Beclèra has made a careful study of the conditions attending the contagion of measles, from which we select his more important conclusions.

Rubeola is contagious from the commencement of the period of invasion to the end of the stage of eruption, a period extending through from eight to ten days. The contagious principle is contained in the secretion of the respiratory mucous membrane, and it still remains to be proved that it has anything to do with the cutaneous desquamation. Although this contagion is diffusible, it is so only to a slight extent, and soon looses its active properties, and does not remain in the rooms occupied by the sick. The period of incubation lasts from thirteen to fifteen days; no immunity is conferrred by the presence of any other eruptive disease.—*Practitioner*, June, 1883.

Idiopathic Cramp of the Tongue and Cremasters.—**Berger** states that cramps localized in the tongue alone are so rarely met with that their existence has been doubted. He describes two cases, however, where this condition was well marked. In both there was bilateral clonic spasm of the protrusors of the tongue. Reflex cremasteric spasms are not rare. But in two cases he observed the spasm was clearly idiopathic. It occurred both by day and by night, each attack lasting two or three minutes; the pain was very great. In one case atropia injections were successful; but failed in the other, where galvanization (from the spine to the scrotum) afforded complete relief.—*Brain*, April, 1883.

Extirpation of the Spleen.—**Albert Blum** gives a tabulated list of splenectomies for wound or hernia of that viscus, dating from 1581 to 1874, all the patients having recovered. To this is added Credé's list of thirty cases of removal for splenic tumor, from 1549 to 1874, with six recoveries. In the latter table every patient who had leucæmia died. Of the recoveries, two were cases of cyst, and four of hypertrophy of the spleen. Extirpation of the spleen, as shown by Credé, Martin, Czerny, and others, is always followed by an increase in the number of white-blood globules, a fact which confirms the physiological theory that the office of the spleen is to transform the white globules into red. After a time, however, the white globules return to the normal proportion, the thyroid gland seeming to take upon itself the functions of the spleen.

Blum draws the following conclusion: 1. When there is a hernia of the spleen, due to a wound, the surgeon is authorized in cutting off the hernial protrusion. All the observations regarding this operation show its benignity and its termination by recovery. 2. Extirpation is contra-indicated in cancer or hypertrophy, either from hepatic or paludal causes. The results of operation in these cases are very bad. 3. Cysts of the spleen are curable by easier and less dangerous means than extirpation of the organ. 4. Extirpation may be indicated in cases of movable spleen if the accidents are serious. In these cases it is relatively easy. 5. It may be affirmed to-day that splenectomy is practicable in man without altering the conditions of health; the operation is only exceptionally indicated. It is difficult to bring it to a safe termination, and there are great chances that it may terminate rapidly in death either by hemorrhage or shock.—*Archives Gén. de Méd.*, June, 1883.

The Bread-pill Cure of Hysteria.—MM. **Landouzy** and **Ballet**, in the *Revue Mensuelle de Médecine*, give the history of an hysterical patient to which it is well to give an extended publicity, not because it presents any novel feature, but as a proof of the scientific errors of those ill-trained minds which attribute the cure of hysteria to supernatural influences. An hysterical patient, twenty-six years of age, who had previously suffered from chorea, was received in the wards of the Charité. There was very marked contraction of the lower limbs, and the patient was unable to execute the slightest movement, not being even able to raise herself in bed. After one or two hypodermic injections of morphia, given at her express desire, she was told that she should have a more energetic remedy, and must use it cautiously. On October 7th, bread-pills were prescribed, and the next morning she related that, wishing to poison herself, she had swallowed the pills: at once the effect was terrible, but soon after she was able to walk a little, and eagerly asked to have another pill; this was accorded, and resulted in her complete recovery. Two days later she helped to clean the wards. In a month's time, she left the hospital.—*British Med. Journal*, May 12, 1883.

The "Shoulder-arm" Type of Paralysis.—**Erb** has shown that in many subjects there is a motor point above the clavicle, opposite the transverse process of the sixth cervical vertebra (corresponding anatomically with the cord formed by the fifth and sixth cervical roots), at which faradization brings about contraction of the infra-spinatus, deltoid, biceps, brachialis internus, and supinator longus chiefly, as well as sensations over the shoulder, and parts innervated by the median. On the other hand, a number of cases of atrophic paralysis have been described in which these very muscles were implicated. Hence it was concluded that in such cases either the gray matter giving origin to the motor roots, or the motor roots themselves of the fifth and sixth cervical nerves were the seat of the lesion. Vierordt describes a case which lends considerable support to this localization of spinal influence. A man after an explosion was found to have received certain injuries. Among other symptoms was considerable swelling above the left clavicle, with loss of power in the corresponding arm. Four months afterwards he was found on examination to have several muscles atrophied and paralyzed, viz., the deltoid, infraspinatus, teres minor, subscapularis, biceps, brachialis, supinators. They all gave degenerative reactions to electrical stimuli. Sensation was abolished over the deltoid; much diminished about the clavicle; diminished over the median area of the hand. Faradization at Erb's motor point on the right side produced contractions of the muscles corresponding to those paralyzed on the left side.—*Brain*, April, 1883.

Atropine in Epilepsy.—Dr. **Max Weiss** gives very complete details of two cases of epilepsy, in the first of which (patient æt. 16) he used a solution of sulphate of atropine gr. $\frac{1}{3}$ to $\frac{1}{2}$ in f℥ijss of distilled water, in doses of gtt. x morning and evening for the first four days. The dose was then increased to about gr. $\frac{1}{25}$ daily, no toxic symptoms being produced. In a month the daily quantity was increased to gr. $\frac{1}{20}$. The other patient was treated in much the same manner, except that oxide of zinc was used at one time with the atropine. Both patients markedly improved, and the medicine being continued, had no epileptic convulsions for more than two months. **Weiss** therefore draws the following conclusions: 1. The bromine preparations when given in large doses always produce disagreeable disturbances of the digestive system, and will be superseded by atropine. 2. Atropine has already lessened, in very small doses, the vehemence and duration of single epileptic attacks, and has lengthened the intervals. 3. Atropine medication is successful in all forms of epilepsy. 4. When it is desired to obtain lasting results from atropine, it must be given in such doses that the lighter toxic symptoms—dryness of the throat and paralysis of accommodation—shall be interrupted. 5. As the atropine medication is continued, the tolerance for it improves so much that the continued administration of gr. $\frac{1}{13}$ a day (in the first case mentioned) produced only very slight toxic symptoms.—*Centralb. für die Gesammte Thérapie*, June, 1883.

Ergotine Hypodermatically in Prolapsus Ani.—Dr. Jette describes his observations with this treatment, first introduced by M. Vidal, at l'Hôpital St. Louis. The preparation is composed of Bonjean's ergotine grs. xv, cherry-laurel water ℥j. It should be freshly made, so as to be of a limpid color and fresh and agreeable odor. The injections are made every other day, commencing with fifteen drops, and, if this is insufficient, going on to twenty or twenty-five. This amount is inserted very slowly into the fibres of the sphincter to the depth of from three-quarters to one and one-half inch. Severe lancinating pain is caused, which then becomes dull and continuous, only ceasing after some hours. After three or four injections contractions of the sphincter and fibres of the intestine commence. A sense of constriction and traction upwards is felt by the patient and observed by the surgeon. Various disturbances may take place; thus, if the doses of ergotine are too weak, there may be frequent desire to go to stool and to pass urine; and when they are too strong there may be spasm of the neck of the bladder, with temporary retention of urine. In some persons M. Vidal observed a tendency to vertigo or syncope, and painful præcordial constriction, with a hard, close, somewhat slow pulse. The later injections become more active, as if cumulative, and cause a more prolonged tenesmus than the early ones. The duration of treatment varies from a few days to some weeks, and seems quite independent of the solution employed, the dose injected, and the intervals observed. To render the cure certain when once effected, it is of importance that three or four supplementary injections should be made.—*Practitioner*, June, 1883.

Injection of Carbolic Acid in Neuralgia.—Dr. Schrumpf publishes in the *Gazette Médicale de Strasbourg* an account of the success which he has met with from the hypodermic injection of carbolic acid in seventeen cases of sciatica, lumbago, cervico-brachial neuralgia, pleurodynia, and muscular pains. Pains which may have lasted for weeks or months are soon relieved, sometimes by a single injection, and at others by four or five, and never requiring more than nine injections. The usual dose was three centigrammes, but in obstinate cases this was doubled or trebled; and Dr. Schrumpf believes that much larger doses may be employed with impunity. He has never found any ill-effect result from the injections, but they are only useful in idiopathic neuralgias, and not in those which are due to spinal disease, compression of nerves, or deeply seated varicose swellings.—*Medical Times and Gazette*, June 16, 1883.

Removal of Tumors of the Bladder.—At a late meeting of the Royal Medical and Chirurgical Society, Sir Henry Thompson reported his experience in the surgical treatment of tumors of the bladder, comprising now in all twelve cases (see The Medical News, Feb. 24, 1883, p. 215). The history, treatment, and histological examination of each of these were given in detail. The total result had been that, out of twelve cases, there had been seven recoveries, more or less partial, and five deaths, In nine cases, the age of the patients was over fifty. In malignant tumors, painful micturition had generally been the first symptom; in innocent tumors, hæmaturia had come first, and pain, if any, later. It had been frequent to find a little florid blood passed at the end of micturition only. Microscopical examination of the cells and fibres to be found in the urine had proved very valuable, though there were some points on which the observer was liable to be deceived; in some cases, villous processes could be found in the urine, and by these the diagnosis was rendered certain. In three cases, calculi had been found to coincide with papillomatous growths, which favored the theory that the papillomata were the result of local irritation. In many cases, only a part of the tumor had been removed; but the author did not consider such cases as by any means necessarily unsatisfactory, for the cicatrization thus produced often led to contraction and consolidation of the remainder. In the hospital-museums of London, there were about one hundred specimens of vesical tumors, which the author had inspected; and of these, as far as he could judge, about sixty were innocent and forty malignant. The label "cancer" he considered to have been too frequently used on the specimens. Out of the sixty cases of innocent tumor, about thirty or thirty-five, as far as could be estimated from their present condition, seemed to have been such as could have been removed, at least in part, by the author's method; and he wished it to be continually borne in mind that any successful operation would have been a clear gain from an otherwise inevitable death; for, without the aid of art, such cases invariably bled to death—some of them needlessly.

Mr. Marshall asked whether his experience of cases, in which no tumors were found on exploration, had furnished him with any certain clue to their diagnosis before operation.

Sir Henry Thompson, in reply, said that the conviction was growing upon him strongly that there were many such cases as would justify operation which were not discovered, or in which operation was not attempted. He considered that cancerous cases should be eliminated by diagnosis before operation, and no operation attempted upon them, but that of the remainder, about one-half could be healed. He started from the hypothesis that all cases of vesical tumor would be fatal, sooner or later, by their hemorrhage or their malignancy, and therefore he regarded operation as the only possible method of cure. Of such cases and method of treatment, he admitted that three years ago he was comparatively very ignorant. Their most frequent history was that they came first under the care of a physician for hæmaturia; then, after a time, pain followed, and a surgeon was called in; he sounded the case, and found no stone; the case passed on to another surgeon, who sounded again without finding stone; the hemorrhage was sometimes supposed to be renal, and the patient was sent back to the country to die slowly of this chronic hæmaturia. That was one reason why so few specimens were to be found in the museums compared with the frequency of the disease. He had himself opened twenty-seven bladders in exploration, and had found only twelve tumors; but he considered that a very good result, for the results of the simple wound, when the neck of the bladder was not cut through, were very slight, and the wound healed rapidly. Four or five years of painful symptoms which were not clearly explicable on any other hypothesis certainly justified an exploratory incision. He had considered the use of nitric acid, and had come to the conclusion that it would do more harm than good.

In two cases in which he had operated for papilloma, he had found a second operation on the remainder of the growth desirable, and that had given him the opportunity of placing his finger on the scar of his previous operation, and of finding that part of the coat of the bladder quite healthy. The mode of operation was admittedly difficult, and he showed many forms of curved and lateral forceps which he had found to give him much greater command of the whole surface of the bladder. He had never attempted to insert the forceps whilst his finger was in the bladder, for he considered that that would almost inevitably injure the neck of the bladder severely, and that was the point which he considered of the greatest importance to avoid, as rendering the healing of the wound very much more dangerous and lengthy.

He described the plan he had found most successful—viz., to insert the forefinger first through the urethral incision, and make a complete examination of the interior of the bladder, so as to feel familiar with the exact position and size of any tumor present; then quietly to withdraw the finger and insert the forceps, guided only by the knowledge he had acquired, and make a decided nip with it with little or no traction; then to withdraw the forceps, reinsert the finger, and remove, if necessary, with the finger-nail, anything that the forceps left incompletely divided. It was often best to leave the detached pieces of the tumor in the bladder for the moment, and remove them all at the end of the operation by the lithotomy scoop. If too much infrapubic pressure were employed, it made the depressed portion of the bladder feel like a tumor; this he attempted to avoid by keeping up the bladder-wall with a ball-probe alongside the forceps, but he was bound to admit that in one case the wall of the bladder had given way after an operation.—*British Med. Journal*, June 16, 1883.

Hysterectomy.—M. Terrillon has successfully employed Schrœder's proceeding, which consists, after removing the tumor, in taking a V-shaped piece from the uterus, bringing the two branches together by means of sutures and then uniting the tendons of the section. It is very necessary that the peritoneum be comprised in the sutures, and that no shred of peritoneum should rest in the wound. M. Terrillon prefers deep sutures. By these the uterine cavity is closed, and there is less danger of septic poisoning. This differs from the old method, in which the pedicle is left in the wound. After the V-shaped piece is removed the uterus is bound by the Cintrat serre-nœud, which prevents hemorrhage. This is removed when the sutures are put in place.—*Journal de Méd. de Paris*, May 19, 1883.

A Successful Case of Removal of a Large Spleen.—A successful case of removal of the spleen in leukæmia, by Fernando Franzolini, of Turin, is recorded in the *Wiener medicinische Wochenschrift*, No. 20. The patient was a pale, delicate woman, twenty-two years of age, who worked in a match manufactory at Paderno. From childhood she had been sickly, and since the age of seventeen menstruation had been irregular, and at times she had suffered from hysterical symptoms. She had never lived in a malarial region, and had never suffered from intermittent fever. In the beginning of the year 1879, without any assignable cause, she began to suffer from severe pain in the left side of the abdomen, which was increased on standing and on pressure. In July, 1880, a splenic tumor of considerable size could be made out, and in January, 1881, an increase of the white blood-corpuscles was noted. The patient was anxious to submit to an operation with the object of obtaining relief, and was admitted into hospital. On admission, the skin and mucous membranes were very pale; there was no œdema, and no enlargement of glands. A tumor could be detected in the left side of the abdomen, which felt elastic, but the boundaries of the tumor could only be ascertained with difficulty. The dulness extended in the long axis twenty-four centimetres (nine and one-half inches), in the transverse axis twenty-seven centimetres (ten and one-half inches). The white blood-cells were five times more numerous than normal. There was no albumen in the urine.

An incision was made along the linea alba to the left of the umbilicus, twenty-two centimetres (eight and one-half inches) in length. The coils of intestine and the large omentum which presented were protected by warm water compresses, and the spleen, with the help of the assistants, was pushed out of the wound. On account of the shortness of the pedicle in the floor of the peritoneal cavity, it was found necessary to place a double silk ligature on the splenic artery, which was the size of the forefinger, and on the vein, which was the size of the thumb. The gastro-splenic ligament included in two ligatures, and the diaphragmatic in one ligature, were divided. The patient lost scarcely a spoonful of blood. The operation lasted eighty minutes. The spleen measured in length 26 centimetres (10¼ inches), in breadth 16.5 centimetres (6½ inches), in thickness 7 centimetres (2¾ inches), and weighed, after removal of 300 grammes (9 ounces of blood), 1526 grammes (52 ounces). Notwithstanding an attack of pleurisy on the left side, accompanied by severe pain and fever, which lasted eight days, the wound healed, and the patient is now perfectly well with the exception of severe uterine pain at the menstrual period. The white blood-cells diminished gradually, and an examination of the blood in January, 1882, four months after the operation, showed almost a normal condition.—*Medical Times and Gazette*, June 9, 1883.

Jequirity in Granular Lids.—Dr. W. A. Brailey reports three cases successfully treated with this new drug, and gives the method of preparing it for use. The seeds, which are extremely hard and tough, are first broken and freed from their shell. They are infused for two hours in cold water, in the proportion of one to fifty; by this time they are so softened as to be easily pounded up, after which they are soaked in the same water for twenty-two hours more. The solution now requires only careful filtration to be ready for use. It is applied to the everted lids, or, when this is impossible, between the lids, thrice daily, till a severe conjunctivitis, of a purulent or diphtheritic type, is produced. He appends a brief summary of certain cases, which may indicate, to some extent, the relative value of this and other methods of treatment. Though it does not, in ordinary cases, immediately destroy all the granulations, it diminishes very considerably the pain and photophobia, and has a decided influence in clearing the cornea. Nor does it appear to affect this tissue injuriously, in which respect we must admit it to be decidedly superior to inoculation from cases of ophthalmia neonatorum. At first, he had considerable hesitation about introducing cases of inoculation with jequirity into the general eye ward; but he has not found that it makes any difference to the progress of other cases, whether operative or not. Though precautions against contagion have naturally been taken, he has not succeeded in inoculating into the sound eye the ophthalmia produced by this agent.—*British Medical Journal*, May 19, 1883.

Iodoform as an Anthelmintic.—Dr. Schildowsky has found that iodoform is a powerful anthelmintic against nematodes. He has used it in three cases with such success, that he believes himself authorized to recommend it. The dose for an adult is gr. j of iodoform mixed with grs. x of bicarbonate of soda. Of course, the dose for a child must be proportionately small.—*Journal de Méd. de Paris*, June 2, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JULY 7, 1883.

BEFORE OR AFTER MEALS?

SUCH is the question often asked of the doctor, but the answer is not always ready. Are there any rules by help of which the decision may be rightly made? One great principle will serve for the disposal of many kinds of prescriptions—that an organ in a state of irritation must be shielded, as far as may be, from the action of irritants. Medicines that are irritating should be given after meals, when the stomach is full, unless the chemical changes which must then occur will destroy their qualities. Mineral remedies, as the salts of copper, zinc, iron, and arsenic, should be given after meals, unless local conditions require their administration in small quantity before meals. Of the latter, arsenic affords a capital illustration. Large doses, acting as an irritant, should follow food, which protects the mucous membrane in a double capacity, but small doses, intended to act on the stomach terminals of the vagi, must be given when the organ is empty. Chemical reasons, also, influence the question of the time for administering mineral irritants. Thus, oxide and nitrate of silver, intended for local action, should appear in the stomach during its period of inactivity, lest, at other times, chemical reactions destroy the special attributes for which these remedies are prescribed. Iodine and the iodides further illustrate this point. Given on an empty stomach they promptly diffuse into the blood, but if digestion is going on, the acids and starch form products of inferior activity, and thus the purpose which they were intended to subserve is defeated.

Substances prescribed to have a local action on the mucous membrane, or for prompt diffusion unaltered, are preferably given before meals. It should not be forgotten that the liver is a great sieve, which retains in its structure for a time, and then excretes, many noxious substances; hence it is, in part, that the subcutaneous administration of many remedies is more effective than the stomachal. The condition of the stomach veins after meals is such as to lessen the activity of diffusion of poisons, and hinders their passage through the liver. It follows that active medicaments in doses near the danger line, are more safely administered after meals.

Probably the most important questions connected with the period of administration of remedies, are those affecting the acidity and alkalinity of the blood and urine. When shall acids and alkalies be given, before or after meals? Here we have to deal with chemical facts that afford small opportunity for differences of opinion, and yet how diverse the views of practitioners; how much more diverse the practice. They must be considered separately.

First, as to acids. When acids are prescribed with the view to check the excessive formation of the acids of the gastric juice, when should they be administered? A moment's consideration given to the laws of osmosis will decide this question. As the blood is a compound fluid with an alkaline reaction, but which furnishes to the gastric glands the materials for an acid secretion, it is obvious that an acid taken into the stomach before digestion begins, will determine, by the laws of osmosis, a flow through the intervening membrane of the alkaline constituents. Hence, when there is an excess in the formation of the acid constituent of the gastric juice, an acid may be given before meals to check the osmosis stomach-ward of the acid-forming materials.

When the alkaline condition of the blood and urine is alike in excess, when shall acids be administered? Obviously in the interval between the digestive acts; for then—the stomach being empty, and the veins flaccid—the most favorable conditions for the diffusion of acid into the blood exist. An alkaline fluid—the blood, on one side of the animal membrane, and an acid fluid, the medicament, on the other, are the conditions most favorable to osmosis. Then the acid diffusing into the blood, and out again from the kidneys, changes the reaction of these fluids from alkaline to acid.

Alkalies require different handling. When an excess of acid exists, as during the progress of digestion, how may alkalies be used? It is a matter of quite common observation that an alkali, as the sodium bicarbonate, will quickly relieve the excess of acid by neutralizing it; but it is equally true, although not as clearly recognized, that the relief thus purchased is at the expense of a continually increasing recurrence of the same malady. It may then be affirmed, as a rule of practice, that the habitual use of alkalies to relieve an excess of acid is unwise and hurtful.

Alkalies are used to increase the formation of acid, when the gastric glands perform this duty inadequately. An alkali given before meals diverts to the gastric glands, by the laws of osmosis, those materials in the blood out of which the acid constituent of the gastric juice is elaborated.

There are two periods when alkalies may be used to lessen the acidity of the urine: just before meals—when the acid-forming materials in the blood diffuse into the stomach glands, and the alkaline medicament diffuses into the blood and outwards into the urine; and after digestion is completed—when the alkalies diffuse directly into the blood, without interference from the contents of the stomach.

The effect of the remedy on the stomachal digestion, must, also, be taken into consideration in deciding on the time for its administration. For example, an alkali taken during the time when the reaction of the stomach juices should be strongly acid, must necessarily hinder, if not arrest, the digestive process for the time being. The metallic salts—notably corrosive sublimate—alcohol, tannin, and some other agents impair or destroy the ferment, or digestive power, of pepsin. Whenever, then, it is necessary to preserve the integrity of the stomachal digestion, the administration of the offending substance must precede or follow the meals at a sufficient interval.

Again there are remedies, which should be given with the meals, such as food adjuncts, and medicines required in the process of tissue construction. Wine that is intended to act as a food, is most beneficial when taken, slowly, during the course of the meal. The objection above stated as regards the ill effect of alcohol on pepsin, is not applicable here, except to the stronger spirituous wines, in large quantity—for the ordinary medicinal wines do not have sufficient alcoholic strength to injure this ferment. Iron, phosphates, cod-liver oil, malt, and similar agents, should, as a rule, go with food through the digestive process, and with the products of digestion enter the blood.

It follows from the foregoing considerations, that the relation of medicine-giving, to food-taking is not merely a question of taste or convenience, or expediency. There are rules capable of exact application, and hence the administration of any medicament may be accurately adjusted to the requirements of the function of digestion.

THE ABORTIVE TREATMENT OF INFECTIOUS DISEASES.

May we ever expect, by internal remedies, to combat successfully those invisible enemies of the human race, which we, at the present day, regard as among the lowest vegetable organisms? Such is the question asked by Prof. Binz, of Bonn, in opening the discussion on the above subject at the recent Congress of German Physicians at Wiesbaden. Those who are familiar with Prof. Binz's experiments (*Centralbl. f. d. med. Wissensch.*, Berlin, 1867) on the action of quinine upon the lower forms of protoplasm, can readily anticipate his answer. In his opinion, we dare not negatively answer this question if a single example can be found of an agent possessing these properties, and he says that we have not only one, but five remedies by which we can reach and render abortive certain causes of disease identical or analogous to the organisms referred to, viz., quinine, mercury, iodine, arsenic, and salicylic acid. Assuming the parasitic origin of malarial fever and reasoning from his experiments which prove the destructive influence of quinine upon vegetable protoplasm, he comes to the conclusion that quinine cures intermittent fever because it destroys the morbific organism in the blood. He brings to bear other facts to prove this proposition, some of which, relating to the culture of the malarial fungus and the effects of quinine upon it, have already been detailed in these columns. For others we must refer our readers to the *Deut. med. Wochenschr.*, of May 2d, where the paper is published. One other fact may be mentioned—all remedies which have heretofore been employed with success against malarial fevers possess antiseptic properties to a greater or less extent. They include quinine, arsenious acid, eucalyptol, beberin, carbolic acid, the sulphites, iodine, and ethereal oil of mustard—quinine being the most efficient, because of the greater tolerance of the nerve-centres towards it.

Similar is the action, according to Binz, of salicylic acid in rheumatism and relapsing fever, of mercury in syphilis, and of iodine in the gummy nodes of the latter disease. We possess as yet no parasiticide for the fungus of tuberculosis and diphtheria, but in this respect we are in the same position we were in relation to malarial fever, syphilis, and acute rheumatism, before the specific properties of quinine, mercury, and salicylic acid were discovered, and there is no reason why we may not still find the coveted parasiticide.

These views of Prof. Binz received no contradiction, and the co-reporter, Prof. Rossbach, of Jena, was confident that such abortive remedies as those referred to, exist for other diseases, and we have only to seek for them systematically to find them. In his judgment the action of salicylic acid and benzoic acid in rheumatism are as certain as that of quinine in malaria, although he admitted that the lower organisms lying at the root of these affections had not yet been discovered. At the same time, their infectious nature is disputed by none.

In marked contrast with the above was a discussion on an allied subject, and held almost simultaneously—that at the Academy of Medicine in Paris upon the treatment of typhoid fever. This was really a report of the results of experience in the treatment of the disease, and not a discussion involving an attempt to establish a theory or doctrine. Both methods are essential to the progress of medical knowledge, and they illustrate also, perhaps, the present bent of thought of the nationalities which they represent.

One member of the Academy had used quinine, another purgatives, another cold baths, another salicylic acid, another digitalis, etc. The participants were all eminent men and of large experience, including MM. Jaccoud, Hérard, Dujardin-Beaumetz, Hardy, and Sée, and their remarks abounded in much practical good-sense.

To the impartial examiner of these reports there is but one conclusion to be reached, and it is that there is as yet no specific treatment for typhoid fever, and that any of the so-called specific measures, whether by cold baths, sulphate of quinine, the antiseptics, or any other remedy, if exclusively relied on, may be not only useless, but harmful and dangerous. The method which recommends itself most to the practitioner of intelligence and experience may be characterized as the *armed-expectant* plan, in which a rigid hygiene and carefully selected diet are secured, as well as a control of all symptoms as they become exaggerated,—colliquative diarrhœa by opium, high temperature by refrigerants and antipyretics, constipation by suitable aperients, debility by supporting measures, etc.

THE GERM OF YELLOW FEVER.

The Department of State has received from Rio de Janeiro an extract from a report by Dr. Domingos Freize, a distinguished physician of Brazil, on an investigation into the nature of the yellow-fever poison. Dr. Freize recognizes in the blood of yellow-fever patients a cryptococcus, to which he has given the specific title of *zanthogenicus*. In the phases of its development it appears as minute points, or as large round cells with grayish or fringed margins, and bright transparent centres. Besides these there are occasionally seen transparent granulations, aggregated in a yellowish matrix.

A gramme of blood charged with these organisms, from a yellow-fever patient, was injected into the veins of a rabbit which died in a quarter of an hour with tetanic convulsions. At first it was suspected that some accident had caused the death of the animal, such as air getting into the vein, or some clot, but in either of these events death should have been sudden and unaccompanied with the symptoms mentioned. At the autopsy visceral congestions were found similar to those seen in persons dead of yellow fever, and the blood was found to contain the cryptococcus which was present in that which had been inoculated.

A gramme of the blood of this rabbit was injected hypodermically into a guinea-pig. which died at the end of some hours. Its blood was found to contain an extraordinary quantity of the cryptococcus. A second guinea-pig was inoculated by hypodermic injection with the blood of the first one, and after some hours the animal appeared feverish and oppressed, with cold ears and paws, trembling, and blackish vomiting. It died in a short time, and its blood showed an infinity of the characteristic organisms.

Dr. Freize considers that these experiments establish the parasitic nature of yellow fever, and that the parasite is the C. xanthogenicus found in every undoubted case of the disease.

He has also discovered and isolated an alkaloid from the black vomit, which he regards as a product or excretion from the microbes. He considers that the color of black vomit is not due to altered blood, but to the cryptococcus. He regards cemeteries as perennial foci of the disease. Some earth was taken from the grave of a man who had been buried the year before. A guinea-pig shut up in a confined space with this earth died in five days. Its blood was literally crammed with the cryptococcus in various stages of evolution; its urine was albuminous, and its brain and intestines yellow with the peculiar pigment of the microbe.

IODINE AND MALARIAL FEVERS.

In the issue of *The American Journal of the Medical Sciences* for July, we find a careful and logical analysis of seventy-six cases of malarial fever treated with the tincture of iodine by Drs. Atkinson and Woods, at Bayview Asylum, Baltimore. The bald facts are, that of seventy-six cases so treated, only sixteen were cured, and in respect to these cures, some doubts may be entertained. As the authors of the paper show, very different, and far more encouraging reports have been put forth from time to time in regard to the antimalarial activity of iodine. Why should such a discrepancy exist? The explanation is to be found, doubtless, in the old source of error—mistaking the *post hoc* for the *propter hoc*—and in the simultaneous administration of remedies, the curative result being ascribed to the wrong one.

Although it may be shown that iodine is not effective as against the paroxysms of intermittent and remittent fever—that it has but little antiperiodic power—it can hardly be doubted that it does remove certain of the morbid products of malarial action. One of the greatest embarrassments experienced in the treatment of intermittent fever, is the prevention of subsequent relapses: partly due to the slow multiplication of the germ, but largely to the structural alterations induced by the preceding seizures, the paroxysms return. Iodine here renders a most important service by removing the changes in the liver and spleen, the pigment deposits, etc. It follows, that quinine having far greater antiperiodic power, is the appropriate remedy to arrest the periodical seizures, whilst iodine should be utilized to remove the products of the infective processes. During the interval between the attacks, iodine, especially iodide of ammonium, should be given in small doses at short intervals, so as to insure diffusion into the remotest anatomical elements.

There is still another point of view from which the administration of iodine in malarial diseases is to be regarded. It is a capital expedient for relieving the excessive irritability of the stomach which, in not a few cases of acute malarial poisoning, interfered seriously with the administration of the antiperiodic. It must be given in small doses for this purpose—from one-fourth to one drop of the tincture at short intervals. Better results are had from a combination of iodine and carbolic acid under the same circumstances. Not only is the combination more effective in allaying gastro-intestinal irritability, but it has also decided antiperiodic power.

HÆMOGLOBINÆMIA AND HÆMOGLOBINURIA.

Under the above title, Ponfick discusses a condition of the blood in which the hæmoglobin is dissolved out of the blood-disk. He showed that a large number of substances possess the power, when injected into the blood, of dissolving the red blood-corpuscles. Among them are the bloods of other species and numerous poisons. The substances in question may, on the one hand, so act upon the blood as to destroy the affinity between the coloring matter and the stroma of the corpuscle, breaking up the latter into innumerable smaller fragments, such being the action of heat and cold (freezing). Or, if it be chemical agents, the stroma of the corpuscle may remain as intact but invisible bodies (Norris' invisible corpuscles?).

An important symptom of such solution is the appearance of blood-coloring matters in the urine, which may, in consequence, be colored red, black, or dirty red. The urine contains hæmoglobin, but no corpuscles. The organism frees itself of the fragments of blood-corpuscles, first through the spleen, which is often quickly distended by them. The freed coloring matter passes first to the liver, and is largely separated with the bile. But to this separation there is a limit, and when it is reached, the coloring matter passes over into the urine.

Even a small quantity of this coloring matter, according to Ponfick, throws the kidneys into a state of great irritability; and the great danger of hæmoglobinæmia, according to him, is an obstruction of the uriniferous tubules, which may produce inflammation with a fatal termination.

Ponfick therefore makes three grades of hæmoglobinæmia: the first in which there is none in the urine, and which is therefore not recognizable; second, that which lasts from one to three days, which may terminate favorably if the tube-casts can be washed out of the uriniferous tubules by increased force of the heart's action, and which is, therefore, amenable to diuretic treatment; and, third, cases in which the tubuli are irremediably obstructed. There may also be in these hæmoglobinæmias high degrees of hæmotogenous jaundice. From facts adduced by Lietheim, Ehrlich, Schumacher, and Ponfick, there would seem to be some relation between syphilis and hæmoglobinæmia.

CYANIDE OF MERCURY IN ATROPHY OF THE OPTIC PAPILLA.

Galezowski maintains that he has often cured atrophy of the optic papilla, syphilitic in origin, by the subcutaneous injection of cyanide of mercury. He employs a solution containing five milligrammes of the cyanide in a gramme of water—about one-twelfth of a grain in fifteen minims. This he injects into the temporal region, daily. If the dose be much increased above this amount, there is danger of inducing an obstinate diarrhœa.

In the course of the discussion on these observations, Rabuteau held that the efficacy of the injection proposed by Galezowski was due to the mercury, and that the cyanogen, so far from contributing to the curative result, was a positive hindrance, because its activity as a poison limited the quantity of mercury which could be administered in this form. Galezowski replied to this in the usual terms. When a practical man's observations are opposed by some scientific statement, he is apt to observe, as Galezowski did to Rabuteau, that no chemical theory is of any value as opposed to practical experience.

REVIEWS.

The Medical and Surgical History of the War of the Rebellion. Part III., Vol. II. Surgical History. Prepared under the Direction of Joseph K. Barnes, Surgeon-General, U. S. A. By Geo. A. Otis and D. L. Huntingdon, Surgeons, U. S. A. 4to. pp. xii. 986, xix. Washington: Government Printing Office, 1883.

With this volume, the Surgical Series of the History of the War is completed. Just how much of it is due to the lamented Otis, and how much to Dr. Huntingdon, is not stated, but the latter pays a justly due compliment to his cultivated and able predecessor, and it is no little praise to say that the work does not seem to have suffered by its completion by different hands from those that laid the foundations so wisely and so well.

After completing the systematic consideration of gunshot wounds by a chapter on the wounds of the inferior extremities, the authors have considered miscellaneous injuries; the complications of wounds, such as ligations, tetanus, wounds of nerves, gangrene, erysipelas, and pyæmia; anæsthetics; and conclude with two chapters on the medical staff and the materia chirurgica, and the transportation of the wounded.

The wealth of material at their disposal has been something marvellous, and no less so the painstaking care and exactness with which it has been utilized. The reader will be struck with the minuteness of detail and the thoroughness with which the subsequent histories of many of the patients have been obtained by correspondence and by research in the Pension Office. The illustrations are both numerous and splendid. Over five hundred wood-cuts and forty beautiful plates, many of them chromo-lithographs, adorn the volume.

To analyze the work, is impossible in the limits of this brief notice. No surgeon can well afford to be without a copy of the work. No surgery will be written within the next century without reference to its facts and figures. *Monumentum ære perennius* must be written upon it. It reflects the greatest credit on its authors and the intelligent liberality of the government that has produced it.

SOCIETY PROCEEDINGS.

MAINE MEDICAL ASSOCIATION.

Thirty-first Annual Meeting, held at Portland, June 12, 13, and 14, 1883.

(Specially reported for The Medical News.)

June 12th, First Day, Morning Session.

The meeting was called to order by the *President*, Dr. George E. Brickett, of Augusta.

Dr. F. H. Gerrish, of Portland, presented a biographical sketch of Dr. Alexander Ramsey, prepared by Dr. George P. Bradley, U. S. N., in 1877.

THE REPORT OF THE TREASURER,

Dr. A. S. Thayer, exhibited an unusually prosperous condition of the Association; notwithstanding the fact that large expenditures have been made, careful management has established the treasury upon a firm basis during the past five years, and has accumulated to its credit a balance of between six and seven hundred dollars.

The Association made a tardy recognition of its duty to its Treasurer, who has served without any compensation, and under a bond, by adopting a standing rule providing for a yearly salary.

A committee was appointed to provide for a Society banquet at the session of 1884.

Dr. S. C. Gordon, of Portland, exhibited a photograph of an

APPARENT HERMAPHRODITE,

whose development on the right side, as seen in the portrait, was unmistakably feminine—long hair, smooth face, and mamma of average size; on the left side the hair was short, a moustache adorned the left half of the lip, and the left side of the chest was flat and covered by a thick growth of hair.

In reply to a question, Dr. Gordon stated that he knew nothing of the appearance of the sexual organs, never having seen the person in question.

Dr. Stanley O. Warren, of Portland, reported a case of

ABSENCE OF THE UTERUS

in a woman twenty-five years of age. Patient always healthy. English descent. First appearance of menstrual blood when eighteen years old; only enough to stain the linen. This was not again present for several months. She thought it came from the vagina. Since last menstruation (?) there has been bleeding at irregular intervals from the rectum, but never enough to be called a flow, only sufficient to soil the linen, and lasting but a day or two.

Married at twenty-one. Intercourse painful, and only accomplished after long and repeated attempts. Half an hour after entrance was effected, there occurred from the vulva a free discharge of dark clots, continuing for three or four days. Sexual desire always present. Dorso-lumbar pains, with ovarian neuralgia and frequent attacks of congestive headache. Frequent severe epistaxis. Physical examination shows feminine development; external genitals normal; vagina, a simple cul de sac, an inch in depth, capable of being lengthened by pressure to admit the entire finger. There is no opening in the vault of the vagina, nor cicatricial tissue to indicate acquired atresia. Ovaries detected by rectal touch connected by a band of firm tissue, which may be a Fallopian tube or rudimentary uterus. No other pelvic organs discoverable by thorough rectal or bladder examination. She is making preparations for another marriage.

A CASE OF CYST OF THE ANTERIOR WALL OF THE VAGINA

was also reported by Dr. Warren. At the operation for its removal by Dr. S. C. Gordon, of Portland, it presented the appearance of a firm and tense tumor, below the base of the bladder, the size of a hen's egg, and having no connection with bladder or urethra. On making an incision a quantity of straw-colored serum escaped. Attempts to dissect away the cyst-wall, after dividing it in a line with the vagina, were ineffectual; the cavity was carefully mopped out with phenol, the upper portion sutured, and drainage established. It was doubtless a cyst of one of Gartner's canals. Further examination disclosed on the right of the vagina a false passage admitting the tip of the little finger, and in depth was two inches. Situated in the vesico-vaginal tissue, it may have been, at some period of life, a cyst like the one opened.

These cases are rare. A case similar, yet differing in one important respect, the cyst apparently communicating with the peritoneal cavity, was reported to the New York Obstetrical Society June 7, 1881.

Afternoon Session.

Delegates were received and welcomed from other medical societies.

The President delivered a short

ADDRESS,

referring to the rise of the Association from a humble birth, in 1853, at the Tontine Hotel, in Brunswick, the seat of the Medical School of Maine. Sixteen of the thirty-one gentlemen who have occupied the president's chair are dead. He expressed strongly his belief that the common welfare of the community demanded that the Maine Medical Association should be unremitting in its endeavors to secure such State legislation as will secure a State Board of Health and a medical registration law.

The question of new remedies and pharmaceutical preparation was recommended as worthy of original investigation.

The Code of Ethics of the American Medical Association was declared to be sufficient, and none too strong for rational, liberal, and intelligent physicians, who ought, above all things, to seek truth.

The report of the committee annually appointed to visit and report upon the Portland School for Medical Instruction was presented by Dr. O'Brien, of Bristol.

The Association then took up for consideration four

CONSTITUTIONAL AMENDMENTS,

two of which provided for such change in the rules for discipline as would remove delegated power from the Censors, and practically convert the Association into a Board of Trial. These were unanimously rejected. Those which provided for the creation of an Examining Board, in addition to the present Board of Censors, were indefinitely postponed.

Dr. Pierce, of Freeport, read a paper on

SYNOVITIS.

Prof. S. H. Weeks spoke of a specimen in the cabinet of the Medical School, which has a heavy chalky deposit not only upon the membrane, but encrusted upon the articular cartilages. In the chronic form, after tapping and application of elastic roller from toes to thigh, passive motion becomes as important as rest in the early stages.

Dr. A. K. P. Meserve, of Portland, read a paper on

ACUTE INFLAMMATION OF THE MIDDLE EAR,

considering the subject from the standpoint of the general practitioner. The rapidity with which tympanic inflammation goes on to effusion, suppuration, and perforation, often rendering it impossible to refer the case to the specialist, until great damage is done to the delicate structures of the ear, demands that the general practitioner should always be prepared to treat this painful and often dangerous affection.

The extreme delicacy of the anatomical relation and physiological adjustment of the several parts of the middle ear, will at once suggest an explanation of the fact that pain is such a prominent symptom of inflammation of this region of the ear, it being usually the first symptom to call attention to the disease. The pain is usually sudden in onset, and agonizing in character, passing rapidly to its height, and only ceasing with effusion or suppuration, or with perforation, of the drum-head. As causative agents, colds, dampness, furuncles in the meatus—the exanthemata especially—scarlatina, typhoid fever, pneumonia, hypertrophied tonsils, pharyngitis or nasopharyngitis, were mentioned.

The course of invasion is through the Eustachian tube; therefore, we should condemn as dangerous the use of the anterior nasal douche.

Inflamed and swollen gums during dentition are a frequent cause. When the hearing power is apparently more acute than normal during the early stages, it may be taken as an indication that the disease is chiefly confined to the membrane, not having involved the deeper structures.

The fulness and subjective noises in the head bear no direct relation to the severity of the disease; they are often absent. Perhaps cases in which these are prominent symptoms recover more slowly than when they are absent; the fever, ordinarily slight, sometimes raises the temperature to 103° Fahrenheit. The superficial or deep-seated redness of the membrana tympani will often enable the practised observer to determine the origin of the disease, though, if the dermoid layer be chiefly affected, the walls of the meatus are likely to be somewhat swollen, thereby interfering with a good view.

The ear should always be examined by the mirror and speculum, and by tests for hearing when practicable, either in child or adult, and especially in children when they awake with a start or scream, or seem disturbed by noises usually unnoticed. Convalescence from any serious disease, or one of the eruptive fevers, is an especial indication to explore thoroughly. By early treatment resolution is hastened, and the serious accidents possible may be averted.

Therapeutical measures for the relief of disease in other parts of the body are also applicable here. Local abstraction of blood by leeches from the region of the ear, and continued application of hot water to relieve pain, may be practised with good effect. The ear should be inflated through the Eustachian tube early in acute inflammation, and especially if there are redness of the throat and signs of extending inflammation therefrom.

The object should be rather to open the tube for the draining away of mucus, than to distend the membrana. A good method is to place one end of a rubber tube in the patient's mouth and the other in one nostril, closing the other nostril and directing the patient to blow through the tube. Paracentesis should be made as soon as demanded by bulging of the drum membrane, and the meatus kept dry with absorbent cotton, and the douche and inflation continued. The constitutional treatment is that demanded for all acute inflammations. Should the case be seen late, or go on to the purulent stage with perforation, the ear may be kept clean by douching with warm water and afterward carefully dried, and the Eustachian tube should be kept open, and the membrane gently brushed over with some mild astringent lotion, Zinci sulphatis gr. i–iij to water ℥j; if the perforation does not readily heal a strong solution of Argenti nitras gr. xl to water ℥j may be added; finely powdered acidum boracicum may be blown into the ear, and if subjective noises are troublesome, blisters may be applied to the mastoid region.

Dr. E. E. Holt, of Portland, said that more attention ought to be paid to this class of cases by the general practitioner; a great number of all diseases of the ear coming to the specialist were chronic in nature. When tested for hearing, the ears should be examined independently. He would not puncture unless he had sure knowledge of the presence of pus. In reply to a query, Dr. Holt said he would not, as a rule, inflate the Eustachian tube in acute inflammation.

Evening Session.

Dr. H. N. Small, of Portland, presented a paper on

EXTRA-UTERINE PREGNANCY.

He said that notwithstanding the fact that extra-uterine pregnancy has attracted during the past few years a great deal of attention; the natural history of this accident does not yet seem to be well understood.

In most cases the cause cannot be decided: the victim may be a primipara or multipara, and we are unable to give any exact explanation. Some light may perhaps be thrown upon the subject by past histories of pelvic inflammations, causing constrictions and displacements of the appendages of the uterus. The gravid sac *has* been found at the ovarian extremity of the tube, which at its uterine end was constricted as by a ligature.

Extreme uterine displacements may prevent the passage of the ovum through the Fallopian tubes. It is reported of a woman who in her first pregnancy underwent Cæsarean section, that becoming a second time pregnant, the child died in the eighth month, gastrotomy was performed followed by death on the tenth day. The unclosed incision of the previous operation was found in the anterior wall of the uterus, through which the fecundated ovum had escaped into the cavity of the abdomen, become attached and developed. Perhaps mental and moral influences may operate as causative agents; the freedom of the lower animals from this accident may be due to the fact that they do not become a prey to emotional disturbances.

Displacements of the ovum is much more frequent in the human female than among those of the lower animals, but that it is confined to the human species, facts disprove.

Some pathological condition of the sexual apparatus is doubtless the prominent cause of this unfortunate occurrence. We have also as causes diseases of the oviduct, temporary flexion, and the obstruction of the tube by mucus.

Apparently the age of the woman has no controlling influence, and by far the most difficult question in such cases is to locate the situation of the ovum. The relative frequency of the different varieties is difficult to determine. Lawson Tait recognizes only two forms. A bursting of the tube may allow the escape of the ovum, and its development may progress among the folds of the broad ligament; or the peritoneum may be also wounded, as well as the fœtal cyst, and the ovum received into the cavity of the abdomen. This is the view taken by other prominent authorities in America. They coincide in the view that the fecundated ovum may be arrested anywhere between the fimbriated extremity of the tube and the uterus, and even in that portion of the tube which passes through the uterine wall. Before the time of quickening, as a rule, the cyst ruptures, and death results from hemorrhage.

Dr. Holt then related the following history of a case of tubular pregnancy occurring in his own practice: In January, 1879, he was consulted by Mrs. T., multipara, for supposed uterine disease; menstruation had been irregular for several months. For six weeks she had not menstruated; was positive that she was not pregnant. Digital examination discovered softening of the os tincæ. Told her, he thought she was pregnant, and asked her to call again in one month. February 10, she had an attack of severe colicky pain, most severe in the left hypogastrium — violent, producing severe prostration. The next morning, she seemed all right again; pain absent, but some tenderness. February 18, a return of all these symptoms with alarming severity. At this visit, felt positive that he was dealing with a case of pregnancy of the left Fallopian tube. Was on the point of summoning counsel, when he was again called, on the 22d, found a new accession of pain in left iliac fossa, with metrorrhagia, all the symptoms of profound shock, and a hemorrhage, the amount of which the slight loss of blood per vaginam was by no means indicative. About two hours before my arrival she was sitting quietly, and suddenly felt as though something had been torn inside. It was now plain that it was tubular pregnancy, and that the cyst had ruptured. Reaction was secured by a free use of stimulants. The abdomen was visibly enlarged, and there was dulness on percussion. The uterus was pushed from its normal position by a mass behind, and on the left side it was a distinct tumor. Ordered opium and brandy *pro re nata*. The next morning, found acute peritonitis. Dr. A. S. Thayer, of Portland, saw the case in consultation. The patient lived about forty-eight hours. At the autopsy, twenty-four hours after death, the abdominal cavity was found to contain a large quantity of blood, with marked evidence of peritoneal inflammation; the left Fallopian tube was much enlarged, and at about two inches from the uterine end it contained a ruptured cyst, and hanging from it a three months' fœtus.

It cannot be expected that extra-uterine pregnancy can be always diagnosed without difficulty. The diagnosis in normal pregnancy is not always certain, unless we can count the beats of the fœtal heart; how much more difficult is it to locate the attachment of an ovum in a Fallopian tube or in the abdominal cavity.

The prognosis of misplaced conception is always grave; the tubal form most fatal, the ventral most favorable. Tubal rupture of the cyst almost always occurs at the third month.

In the present state of abdominal surgery if the diagnosis be positive, there is no reason why we may not operate to advantage and remove the cyst. If the cyst has ruptured, it seems there is but one resort, and that of but little promise—to cut down, ligate the bleeding vessels and perhaps remove the cyst. Certainly we ought to give the patient the benefit of all measures, even the most extreme when the probability is only certain death.

DR. S. C. GORDON believed that we could not overestimate the value of bimanual palpation in establishing a diagnosis. He regarded Rockwell's method of electro-therapy the best treatment, and in failure of this, should unhesitatingly take the chance offered by abdominal section.

PROF. F. H. GERRISH gave a description of a specimen in the cabinet of the Maine Medical School. It is a fœtus contained within a calcareous mass, removed from the abdominal cavity of a woman who died at the age of 60, after bearing several children, subsequent to the symptoms which marked the development of this tumor during her early married life. Dr. Gerrish offered this as bearing upon the question of prognosis.

DR. MESERVE reported a case of death from peritonitis, following a train of symptoms pointing to extra-uterine pregnancy. No post-mortem could be obtained.

Cases in which the occurrence of the accident was discovered at post-mortem, were reported by Drs. Hutchinson and C. G. Adams.

DR. S. H. WEEKS, Professor of Surgery in the Medical School of Maine, presented a verbal communication on the

NATURE AND TREATMENT OF FRACTURES ABOUT THE ELBOW-JOINT.

The different varieties were indicated by specimens, and their treatment illustrated by the exhibition of several pieces of fracture apparatus. That advocated as fulfilling the greatest number of indications was an immovable angular elbow splint made from wood, tin, sole-leather, or gutta-percha. Early and judicious passive motion was as essential at the proper time as the fixed dressing.

DR. GORDON illustrated a method whereby constant extension might be made by a hinged wooden splint, binding upon the anterior surfaces above and below the joint, a stiff flat spring of metal or gutta-percha.

DR. GERRISH spoke of the necessity of treating certain forms of this class of fractures by straight position and plaster splints.

JUNE 13TH, SECOND DAY.

MORNING SESSION.

DR. O. A. HORR, of Lewiston, presented the report of the committee appointed to visit

THE MEDICAL SCHOOL OF MAINE.

The school and its interests were commended to the members of the profession, and a favorable report made of the work accomplished in the several Chairs. A change of location from Brunswick to Portland was urged, to be brought about as soon as practicable for the sake of the increased clinical advantages offered by the hospitals and dispensaries of the city.

DR. E. E. HOLT, of Portland, read a paper upon

DISEASES OF THE MASTOID,

in which he gave the statistics of forty cases from private practice, in two thousand cases of diseases of the ear, showing that the left ear was involved three times as often as the right. The treatment was embrocations, hot-water poultices, leeches, Wilde's incisions, and perforation of the bone according to the indications. As regards results, twelve males and six females were recorded as cured, four each as "improved," "unknown," "not treated," and "died." Seven remained under treatment. In two cases of death, the purulent condition was such that nothing was done. In one, an operation was advised, but refused, and the patient died after exhibiting cerebral symptoms. In the other case, the disease came on in the latter part of pregnancy in connection with acute suppuration of the tympanum, and in the absence of pronounced indications for opening the mastoid, or even using Wilde's incisions, operative interference was deferred until a prominent swelling appeared at the root of the zygomatic process, when an incision liberated pus and revealed a rupture of the bone; a fatiguing gestation, difficult labor, exhausting inflammation and suppuration of the tympanum and mastoid brought on a fatal termination.

Several preparations of the temporal bone were exhibited, showing the anomalous course of the lateral sinus, and indicating the care necessary in drilling this bone. Several sequestra removed by operation were shown, and a part of the cochlea which had ulcerated away in connection with mastoid disease, the patient making good recovery.

DR. A. H. BURBANK, of Yarmouth, read a paper on

THE INDUCTION OF PREMATURE LABOR

for those cases in which, if allowed to go on to the full term, it is reasonably sure that delivery must be effected by craniotomy, or version, or abdominal section. It is demanded when there is a conjugate diameter of the brim so small as two and one-half to three and one-half inches. When that diameter does not exceed two inches and one-half, or two inches and three-quarters, the time of operating must not be later than the end of the seventh month. The operation should not be deferred beyond the end of the eighth month when the conjugate diameter is not more than three inches and a half. Rare and exceptional cases may require it before this period, but it would then be resorted to wholly in the interests of the mother, and with but a faint hope of saving her offspring.

Manual and instrumental methods of pelvimetry were compared, the necessity for the obstetrician to gain all possible information from his patient as to any history of defective ossification, and the character of previous labors, if a multipara, was insisted upon. Two cases were detailed in which, by his method, the Doctor had safely delivered in the one case two children now living, one at seven, the other at seven and a half months of pregnancy; craniotomy having been performed in an earlier labor. In the other case, a child, now living, was delivered at seven months and three weeks. This patient had previously been delivered by perforation in her first, and by forceps at seven months in her second and third pregnancies, of living children, both of which survived for a few weeks.

The method of procedure was then detailed as follows: "Directing the patient to lie upon her left side, I strongly depress the uterine globe, with the right hand upon the fundus uteri, while I pass the index finger of the left hand through the os. Then, with the finger slightly bent and its palm towards the symphysis pubis, I steadily draw the cervix in that direction, and expect, in a half hour, to have a dilatation the size of a half-dollar or more. Some labor-pains are generally caused by each attempt to dilate, but they will soon cease. Deeming it unfortunate for labor to be induced before thorough dilatation and dilatability are secured, and for reasons to be hereafter given, not expecting or desiring labor to follow for some days, I leave the case for twenty-four hours, and at the next and at subsequent visits the os is more easily reached (always with the left hand), and I am able to effect further dilatation by drawing the os toward the symphysis, first with one finger and as soon as I can with two and three fingers; or after three attempts at dilatation, two fingers in the os can be separated from three to four inches, and sufficient dilatation has been secured to warrant inducing labor-pains. I have then given somewhat less than a fluiddrachm of extract of ergot, each five hours until labor has commenced. If at the end of twenty-four hours labor is not induced, it has been sufficient to increase the dose to one drachm at the same intervals. For this purpose, and administered in this way, ergot has seemed an available agent and entirely safe for mother and child."

In explanation of these methods it was insisted that their value lay in a very *slow* and *patient* use of means in the preparatory stage.

With respect to the use of bougies, and the practice of allowing them to set up uterine action by remaining in the uterus some specified time, the writer could not appreciate the advantage of uterine action before dilatation, rather than after it.

Artificial dilatation, as described, is a comparatively painless operation; over other methods it has the advantage of being as fully efficient, less painful, does not confine the patient to her bed beyond the half hour in each day required for the operation, and permits her to be about her ordinary employment until labor begins.

In exceptional cases (puerperal eclampsia), when the saving of time is an element, a more rapid and persistent manual dilatation aided by Barnes' dilators is effective.

The time occupied by Dr. Burbank in inducing labor, has been from two to four or five days. This length of time is to be preferred, for in an unnatural process the tissues are taken by surprise and the operator must accommodate himself to them; hence, it is better to be satisfied with a good result even if arrived at slowly. After the initiatory steps in dilatation have been effected, a change in the vagina, vulva, and perineum will be appreciable, and the difference between the termination of this induced labor, and one conducted by nature will be slight.

Experience has shown no danger to the mother in eleven operations; in each case, except one delivered by forceps, the labors have been short, without accident, and in all respects natural. The convalescence has been invariably, speedy, sure, and without apparent danger.

The same assurance of safety cannot be bestowed upon the children. Of eleven born permaturely, ten were born alive; of this number, one which came at six and a half months lived but three days; seven of the remaining nine were born at seven months and over, and are now alive. Extra care should be bestowed upon these prematurely born children; thick wraps of cotton should be prepared for enveloping them, and the usual ceremonies of washing should be dispensed with; the limbs should be often examined, and if necessary, exposed to heat from an open fire, stove, or register; washing ought to be prohibited until the child shall arrive at that age at which it would have been born; instead, daily anointing the whole surface with mild unguents, and removing gently portions thereof, must suffice for cleanliness. Till these immature infants cease to live upon borrowed time, they must be kept enveloped in the cotton wrap.

DR. MITCHELL, Prof. of Obstetrics in the Medical School of Maine, agreed as to the value of manual dilatation, as a means of inducing labor, but preferred the insertion of a bougie to ergot; he would especially recommend Dr. Burbank's method in *all* cases of placenta prævia, and had seen a case of obstinate chorea, in a pregnant woman, relieved and cured by this procedure.

DR. GORDON saw serious objections to such manual interference with the cervix, and condemned the use of ergot as dangerous to mother and child in first and second stages of labor, and uncalled for in the third stage, unless for hemorrhage.

DR. J. T. DANA gave an interesting review of the several forms of

BRIGHT'S DISEASE,

considering pathology and symptomatology and treatment of those conditions known as tubal nephritis, amyloid kidney, and cirrhotic kidney.

PROF. MITCHELL, of Brunswick, believed that the prognosis of chronic Bright's disease is becoming more favorable. His success had been largely due to the milk treatment, and he had seen marked benefit from the use of chloride of gold in the cirrhotic form.

DR. PENDLETON reported a fatal case in which, at the post-mortem, a marked cirrhotic condition of the kidney was found, but the patient had exhibited no prominent symptoms except neuralgia of the orbit, a small amount of albumen, and a few casts, until a day or two before death; there was no œdema, no effusion.

DR. J. A. SPALDING, of Portland, read part of the testimony in a suit for malpractice in

A CASE OF INJURY TO THE EYE.

The plaintiff's eye had been destroyed by a thrust from a cow's horn, and (as the plaintiff maintained) so badly treated by the defendant physician, that sympathetic ophthalmia ensued and destroyed the sight of the other eye. The jury gave a verdict for defendant on the ground that an ordinary physician could not be expected to know all about such cases. The jury may also have been influenced by the opinion expressed by several medical men and specialists, that if the defendant told the plaintiff's friends of the danger of sympathetic ophthalmia and urged enucleation, he did his duty and ought not to be held responsible. The essayist then proceeded to examine the case in its various details, and to show briefly the generally accepted ideas of treatment and the indications for enucleation after injuries of the eye. Every eye that experience teaches us is liable to set up sympathetic ophthalmia ought to be removed at once.

Three cases of injury to the eye from a cow's horn were compared: in one, sympathetic ophthalmia destroyed the fellow eye; in a second, the sight was partially destroyed by sympathetic ophthalmia but was already improving rapidly when enucleation of the injured eye was made for the relief of exquisite pain; in the third case, the injured eye recovered excellent sight without treatment, although both iris and lens were thrust out, while the fellow eye was never sympathetically affected. These results in cases so similar, tend to show the extreme degree of doubt that must ever prevail in cases of injury to the eye. Every physician should therefore decide at once what he is to do, and if in doubt, consult the larger experience of the specialist.

AFTERNOON SESSION.

Drs. Ayer, of Boston, and Colony, of Fitchburg, delegates from the Massachusetts Medical Society, were introduced.

The Association then proceeded to the

ELECTION OF OFFICERS FOR 1883.

President.—Dr. O. A. Horr, of Lewiston.

Vice-Presidents.—Drs. L. W. Pendleton, of Portland, and D. E. Marston, of Monmouth.

Recording Secretary.—Dr. Charles D. Smith, of Portland.

Corresponding Secretary.—Dr. J. O. Webster, of Augusta.

Treasurer.—Dr. A. S. Thayer, of Portland.

Board of Censors.—Drs. H. N. Small, of Portland; W. K. Oakes, of Auburn; J. M. Bates, of Yarmouth; W. B. Cobb, of Standish; and J. D. Nutting, of Hallowell.

DR. M. C. WEDGEWOOD, of Lewiston, then delivered

THE ANNUAL ORATION,

his subject being *Rational Medicine and Quackery.*

Rational medicine was defined as a practice founded on reason; that system of practice which appeals to and which can be comprehended by our reasoning faculties. It discards all "pathies;" it refuses to admit or recognize any man who adopts exclusive ideas as to the theory of disease or methods of cure. It collects, systematizes, and utilizes every grain of truth, and conceals or treasures for exclusive use nothing. Quackery flourishes from an inherent weakness of the human mind; it is the stamp of ignorance and superstition, and belongs to all trades and professions. No field is so wide for its cultivation as that of medicine; and we find it practised by men who have diplomas and belong to reputable medical societies, as well as by pretenders. We offend against rational medicine by the practice of such habits as detract from the dignity and honesty of an honorable profession.

DR. B. F. STURGIS, of Auburn, reported a case of

CHRONIC ABSCESS OF THE TIBIA

relieved by perforating. Having broken the central pin of his trephine, the operator used a gouge and chisel, and evacuated pus from two cavities, one, two inches long and three-fourths of an inch wide, near the head of the bone, below the anterior surface; the other below, of about the same size, and separated from the first by a dense septum of bone. The cavities were washed out with carbolized water, and packed with oakum and balsam of Peru. Recovery was rapid and without unusual symptoms.

ABNORMALITY OF THE BLADDER.

DR. F. H. GERRISH, of Portland, reported a case in which the bladder was divided by a vertical septum into two nearly equal portions. A sound easily reached a stone in the posterior chamber, but a lithotrite with its shorter beak failed to reach it, slipping always into the anterior cavity. After prolonged efforts with the lithotrite on two occasions, lateral lithotomy was performed and the calculus extracted. The patient, though seventy-five years old, did not have an alarming symptom after the operation.

THE COMMITTEE ON THE PRESIDENT'S ADDRESS

reported, through the Chairman, Dr. S. H. Weeks, the following:

Resolved, That the sanitary interests of this State imperatively call for the establishment of an efficient State Board of Health.

In accordance with this resolution it was urged that a committee of three be appointed, with power to add to their number, and instructed to make all needful investigation and present the subject to the next Legislature with the request that such action may be taken as deemed best for the health and prosperity of the people of our State.

Resolved, That it would be for the interest of this Association to have presented at each annual meeting all advances made during the previous year in materia medica.

In accordance with this resolution we recommend the appointment by the Board of Censors of a committee on new remedies.

Dr. Horr, of Lewiston, a member of the last Legislature, gave some interesting facts with reference to the rejection of the bill to secure

MEDICAL REGISTRATION.

The bill had its origin in the Androscoggin County Medical Society. Physicians throughout the State were invited to coöperate to secure its passage. Everything seemed favorable at the hearing before the legislative committee; opposition came from eclectics and spiritualists through the country members. The bill was subsequently amended to a condition hardly better for the regular profession than no bill at all. It passed a second reading in the House, was amended in the Senate, then refused concurrence by the House; the Senate adhered to its action, and a State Legislature which has incorporated almost anything asked for in the way of hybrid medical colleges and bogus literary societies, strangled a measure which, if not in all respects perfect or satisfactory, would have been a step towards legalizing and protecting the honorable practice of medicine.

Evening Session.

Dr. S. C. Gordon, of Portland, read a paper on the

RESULTS OF SOME OF THE OPERATIONS FOR ACCIDENTS OCCURRING AT PARTURITION.

The points emphasized in this paper were:

1. The importance of operating for a definite purpose. The various accidents are sooner or later followed by certain well-marked symptoms, and unless the operations are performed with special reference to relief of such symptoms, the patient is not benefited; a mere closure of a lacerated cervix is by no means a cure of the symptoms arising therefrom. To insure the greatest possible success, the complete removal of all cicatricial tissue must be made along the entire length of the laceration.

2. That the operation for cystocele has proved extremely efficient and satisfactory when the ovoid-shaped denudation has been made, removing as much tissue as will allow a coaptation of surfaces without undue strain upon the sutures, and care is taken that all hemorrhage ceases before uniting.

3. That removing a V-shaped portion from each side of the cervix as high as the vaginal roof, and uniting the surfaces, is the essential step in reducing chronic alveolar hyperplasia of the uterus; if in connection with this we have retroversion, *it should be replaced at the same time*, and the uterus supported with a pessary until the operation of perineorrhaphy is made, when the pessary is to be removed. These points carefully observed, *cure retroversion in a very large percentage of cases.*

4. The extreme care necessary in making these operations:

a. In not operating for lacerated cervix while fungous growths remain in the uterus, or catarrh exists in the cervix.

He thought much time is often lost in preparatory treatment through fear of pelvic inflammation. When only neuralgic pain is left, the latter is not relieved until the operation is made.

b. In using no more sutures than are absolutely necessary to coapt the parts and stop hemorrhage. He believes many operations fail from neglect of this latter caution.

c. In never allowing the use of the catheter after any of the operations if the patient can pass the urine herself. Also in keeping the bowels open from the first.

Thursday, June 14th, Third Day.
Closing Session.

THE REPORT OF THE BOARD OF CENSORS

recommended that the next annual meeting be held in Portland, on the second Tuesday of June, 1884; exonerated Dr. Calvin Seavey from charges preferred against him, on the ground that they were not sustained; asked for the passage of a standing rule requiring all candidates for membership to appear before the Board on the first day of the annual session, and produce diplomas or satisfactory evidence that they possess them; and made the following appointment:

Orator.—Dr. A. S. Hersey, of Oxford.

The report was accepted, and its recommendations adopted.

The President announced as

Committee on State Board of Health.—Drs. I. T. Dana, of Portland; J. M. Bates, of Yarmouth; S. H. Weeks, of Portland.

Committee on Medical Registration Bill.—Drs. O. H. Horr, of Lewiston; J. O. Webster, of Augusta; O. St. C. O'Brien, of Bristol; J. B. Walker, of Thomaston; A. R. G. Smith, of Whitefield.

After the customary votes of thanks, the Association adjourned, having completed one of the most satisfactory sessions for many years.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, April 4, 1883.

The President, Alfred Stillé, M.D., in the Chair.

Dr. J. Solis Cohen read a paper entitled

DOES EXCISION OF THE LARYNX TEND TO THE PROLONGATION OF LIFE?

That complete laryngectomy can be performed without sacrifice of life, he said, there is now cumulative evidence. That every operation involving the removal of the larynx imperils the immediate existence of the patient, the records of the procedure abundantly attest. That a very large proportion of the subjects operated upon, say nearly fifty per cent. of them, succumb within so brief a period that their deaths may be justly attributed to the operation, an examination into its statistics renders only too obvious.

The writer owns to a prejudice against the operation; he has never witnessed a laryngectomy, nor seen a patient upon whom it had been performed. It may seem rather an assumption on his part, therefore, to criticise an operation, of the technical procedure and after-management of which he is practically ignorant.

Let us consult the statistics of the operation, and contrast the average life of those who have been subjected to it with the average life of patients, in similar condition, entrusted to palliative treatment.

I have before me, as I write, more or less detailed records of sixty-five operations of complete "extirpation of the larynx," as it is termed.

There are a number of partial excisions which have not been included in the number, because the partial operation is not within the scope of this paper.

Of the sixty-five complete operations, four were performed in non-malignant cases; one for cicatricial syphilitic stenosis, with death "some weeks after from pneumonia" [Watson]; one for necrosis, the case terminating fatally by marasmus five days after the operation [Rubio]; one for polypi of the larynx [Ruggi]; and one for papilloma of the larynx [McLeod].

Of the sixty-one operations remaining in this list, five were performed for sarcoma; in two of which the results were so remarkably exceptional, that attention should be especially directed to them.

I.—Bottini, of Turin, on Feb. 6, 1875, removed the entire larynx from a male subject twenty-four years of age, with a laryngeal sarcoma, partly round-celled, partly spindle-celled. Notwithstanding copious hemorrhage and severe erysipelas, the patient recovered. He was reported well in August, 1881, or more than six years after the operation, and I have seen no notice of his death. He had been performing the duties of a postman, and walking eight miles a day. This is the most successful case on record.

II.—Caselli, of Reggio-Emilia, on Sept. 20, 1879, removed the larynx, pharynx, base of the tongue, soft palate, and tonsils from a female subject, nineteen years of age, for a sarcoma of the larynx, pharynx, palate, and base of tongue. The patient was reported well in August, 1881, practically two years after the operation, and I have seen no notice of her death. This is the second best case on record.

The remaining three patients operated upon for sarcoma died at the periods of seven, fifteen, and seventeen and a half months respectively:

Table I.—Cases of Sarcoma.

1 (Lange) lived nearly 7 months.
1 (Czerny) " " 15 "
1 (Foulis) " " 17½ "
1 (Caselli) was alive Aug. 1881, nearly 2 years after the operation.
1 (Bottini) was alive and well Aug. 1881, 6½ years after operation.

Taking tor granted, as we are bound to do, that death was imminent in these five cases of sarcoma when the operation was resorted to, we have a considerable prolongation of life in every instance, and a remarkable prolongation in two, or in forty per cent. As far as these limited statistics go, therefore, the operation of excision of the larynx in hopeless cases of sarcoma is worthy of the serious consideration of the surgeon.

The history of the remaining fifty-six operations presents a much more gloomy account. They were all for carcinoma, if we may include under that head Schede's case of "cancroid."

Let me read the list of deaths as far as reported:

Table II.—Recorded Deaths after Laryngectomy for Carcinoma.

1.	Tilanus, . .	Death in	36 hours	from	collapse.
2.	MacEwen, . .	"	3 days	"	pneumonia.
3.	Bottini, . .	"	3 "	"	pneumonia.
4.	Langenbuch,	"	3 "	"	collapse.
5.	Schmidt, . .	"	4 "	"	collapse.
6.	Gerdes, . .	"	4 "	"	collapse.
7.	Billroth, . .	"	4 "	"	pneumonia.
8.	Toro, . . .	Death in	4 hours	from	pulmonary emphysema.
9.	Schönborn, .	"	7 "	"	?
10.	Multanowski,	"	5 "	"	pneumonia.
11.	Reyher, . .	"	5 "	"	septic broncho-pneumonia.
12.	Pick, . . .	"	5 "	"	pleurisy and pericarditis.
13.	Reyher, . .	"	7 "	"	septic broncho-pneumonia.
14.	Reyher, . .	"	7 "	"	septic pneumonia.
15.	Watson, . .	"	7 "	"	pulmonary embolism.
16.	Thiersch, . .	"	7 "	"	"secondary infectious" pneumonia.
17.	Albert, . .	"	8 "	"	"diffuse bronchitis and lobular" pneumonia.
18.	Reyher. . .	"	11 "	"	"hypostatic" pneumonia.
19.	Reyher, . .	"	14 "	"	exhaustion.
20.	Maas, . . .	"	2 weeks	"	pneumonia.
21.	Watson, . .	"	2 "	"	pneumonia.
22.	Bircher, . .	"	16 days	"	pneumonia and "pulmonary gangrene."
23.	Hahn, . . .	"	25 "	"	putrid bronchitis.
24.	Billroth, . .	"	6 weeks	"	passage of bougie into mediastinum.
25.	Multanowski,	"	2 mos.	"	recurrence.
26.	Gussenbauer,	"	2 "	"	tuberculosis pulmonum.
27.	Multanowski,	"	3 "	"	"croupous" pneumonia.
28.	Langenbeck,	"	4 "	"	recurrence.
29.	Thiersch, . .	"	4 "	"	recurrence.
30.	Novaro, . .	"	4 "	"	recurrence and hemorrhage consequent upon additional operative procedures.
31.	Von Burow, .	"	4½ "	"	sudden suffocation.
32.	Czerny, . .	"	5 "	"	recurrence.
33.	Volker, . .	"	5 "	"	suffocation.
34.	Heine, . .	"	6 "	"	recurrence.
35.	Maas, . . .	"	6 "	"	recurrence.
36.	Billroth, . .	"	7 "	"	recurrence.
37.	Bruns, . . .	"	9 "	"	recurrence.
38.	Kosinski, . .	"	9 "	"	recurrence.
39.	Reyher, . .	"	9 "	"	recurrence.
40.	Czerny, . .	"	15 "	"	recurrence.

To this list may be added the cases of—

Margary, in which recurrence was reported at 3 months.
Kocher, " " " 7 "

In the following cases neither death nor recurrence has been reported:

1.	Foulis, . . .	alive five weeks after operation.
2.	Czerny, . . .	alive six weeks after operation.
3.	Schede, . . .	artificial larynx adjusted two months after operation.
4.	Mayal, . . .	no recurrence three months after operation.
5.	Von Bergmann,	alive "some" months after operation.
6.	Wegner, . .	alive seven months after operation.
7.	Whitehead, .	"no recurrence;" alive eight months after operation.
8.	Winniwarter, .	"no recurrence;" alive eleven months after operation.
9.	Gussenbauer, .	well fourteen months after operation.
10.	Kocher, . .	no recurrence sixteen months after operation.
11.	Thiersch, . .	well seventeen months after operation.
12.	Thiersch, . .	well eighteen months after operation.
13.	Gussenbauer, .	well nineteen months after operation.
14.	Hahn, . . .	well two years after operation.

Of the forty reported deaths, seventeen, or forty-two and a half per cent., occurred within eight days, and five more succumbed within the second period of eight days.

The danger during the first few days is from shock and from pneumonia. Very few have perished from direct shock, very many from pneumonia. The pneumonia has been attributed generally to the ingress of blood, aliment, and septic materials into the air-passages; but if I may form an opinion from what I have witnessed in many other operations upon the neck, there is a certain amount of risk of pneumonia in all surgical interferences in the cervical region, even when the air-passage is not opened. Thus I have seen it follow extirpation of the thyroid gland, extirpation of cervical neoplasms, and even exploratory incision into the region. It may be that the reduction of temperature to which the pneumogastric nerve is subjected, leads to pneumonia, and that the manipulations within the wound render it especially sensitive. When we reflect that the majority of these operations of laryngectomy consume from one to three hours in their performance, we can fairly presume that the pneumogastric nerve is subjected to sufficient ordeal to excite an early pneumonia, quite independently of access of foreign matter to the lungs; a sequel of the operation against which every available precaution is taken.

The danger from pneumonia does not seem to exist longer than two weeks, for we have but one record of death from this cause after the sixteenth day, and that from "croupous pneumonia," at the end of three months. This important fortnight safely passed, the life of the patient appears comparatively secure up to the fourth month. At the fourth month, death begins to be imminent from recurrence, and we have, in our table, three at four months, one, and possibly several, within five months, two at sixth months, one at seven months, three at nine months, and one at fifteen months. One death from recurrence is reported at two months after operation. Nine cases are reported living at seven, eight, eleven, fourteen, sixteen, seventeen, eighteen, nineteen, and twenty-four months, respectively. Thus forty-two and one-half per cent. of the forty cases recorded as terminating fatally, or more than thirty per cent. of the entire number operated upon for carcinoma, perished within eight days; and at the end of the six months, thirty-five of the forty were dead, or eighty-seven and one-half per cent., making sixty-two and one-half per cent. of the entire fifty-six operations for carcinoma; with great probability of a still higher percentage had all the deaths been reported.

Let us contrast this record with the average life of carcinoma of the larynx not subjected to the radical operation of laryngectomy.

Of a number of cases of carcinoma of the larynx under my own care, who agreed to submit to exsection of the larynx should I so determine, and in whom I performed tracheotomy in preference, one lived six months, two lived seven months, one lived thirteen months, and one lived eighteen months, respectively, after the tracheotomy.

Had laryngectomy been practised in these five cases, with equal tenure of existence, the result would have been accredited to the radical procedure. Had the operation been performed, one life might possibly have been prolonged; the majority, however, would probably have been shortened. At the period at the end of which eighty-seven and a half per cent. of the recorded deaths after larygectomy had occurred, *i. e.*, six months, all my tracheotomized cases were living; and but two of the entire number of fifty-six excisions for carcinoma outlived the longest-lived instance in my tracheotomized list. It is not improbable that a complete series of collated statistics would present a far better exhibit for the cases merely subjected to tracheotomy and palliative procedure. It is generally believed that the natural history of carcinoma of the larynx comprises an average existence of about two years and a half; tracheotomy becoming requisite at a period varying from nine to eighteen months, according as the disease is wholly intra-laryngeal or more parietal.

In laryngectomy, the initial shock is severe, and sure to carry off a large percentage of cases by collapse, or by pneumonia. A certain number of lives are sacrificed; and the condition of the survivors, with their artificial substitutes for the larynx, is often described as pitiable in the extreme.

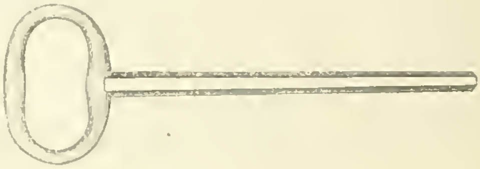
In tracheotomy, there is little shock, very slight danger of pneumonia, and much less risk of septic infection. Life is not likely to be sacrificed in any instance; and existence is much more comfortable after the operation than after laryngectomy.

For these reasons, excision of the larynx for carcinoma does not, in my opinion, tend to the prolongation of life; for the prolonged existence of a very few, seems purchasable only at the sacrifice of the remnants of existence of many others. The greatest good to the greatest number, appears better secured by dependence on the palliative operation of tracheotomy.

DR. W. B. HOPKINS described

A SIMPLE CONTRIVANCE FOR ROLLING BANDAGES.

It consists of a Coats' key having an eight-sided shaft four inches long, such as is used in the ordinary bandage-machine. The shaft tapers from one-quarter of an inch in diameter at the shoulder to one-fifth at the tip. The tip is made quite smooth in order to revolve easily in the palm of the hand.



Reduced one-half.

After fixing the terminal extremity of the bandage upon the shaft, the key is made to revolve by the right hand, the left holding the tip of the instrument in its palm, guiding the bandage, and giving the requisite tension.

THE PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Conversational Meeting, April 26, 1883.

THE PRESIDENT, JAMES TYSON, M.D., IN THE CHAIR.

DR. CHARLES K. MILLS read the paper of the evening, on the

METHODICAL EXAMINATION OF THE BRAIN,

which was amply illustrated by diagrams and specimens prepared by Dr. Mills, and also by a series of preparations from the Mütter Museum of the College of Physicians of Philadelphia.

Dr. Mills passed by with brief allusions the examination of the scalp, skull, and membranes of the brain, the cerebral spaces and vessels, and the best methods of determining volume, specific gravity, and cranial capacity. His chief object, he said, was to discuss and demonstrate the proper procedures to be pursued in methodically examining the surface and interior of the brain after the removal of its envelopes, for the purpose of discovering and accurately localizing lesions.

In order to make an autopsy of the brain proper in a rapid, methodical, and scientific manner, he considered several requirements necessary:

1. The superficial topography of the brain should be understood. The examiner should be able to pick out without hesitation the chief fissures and convolutions. He should also, of course, be perfectly familiar with the numerous superficial subdivisions of the base of the cerebellum.

2. The variations in the size, direction, or arrange-

ment of cerebral fissures and convolutions most likely to occur, should be known to him. Age, race, individual type, education, and other causes, act to produce variations and anomalies. The student thoroughly familiar with the diagrams and demonstrations of Ecker might find himself at sea in his first examinations if this fact is not remembered.

3. A knowledge of the internal structure of the brain should be possessed by the operator. He should understand not only its ventricles and horns, its commissures and peduncles, its foramina and aqueducts, but also its medullated structure, as exhibited by sections of the cerebral and cerebellar hemispheres made in various directions. Methodical cerebrotomy, practised in the vertico-transverse, vertico-longitudinal, horizontal, and even in other directions, will give certain more or less fixed appearances, which should be familiar.

The surface of the brain should be thoroughly examined for morphological peculiarities, such as deficiency or excess of fissures and gyri, confluence of fissures, simplicity or complexity of folds and furrows; and also, of course, for pathological changes, for atrophy, softening, hemorrhages, changes of color, etc. Dr. Mills described the fissures and convolutions as given by Ecker, and also called attention to some of the most common and striking variations from the usual type of the adult human brain, dwelling particularly on the fissures most likely to be confused—the precentral, central, and retro-central, etc. The views and observations of Moritz Benedikt on the brains of criminals were referred to and criticised.

The examination of the fissures, convolutions, cranial nerves, and various regions of the surface of the cerebrum and cerebellum having been completed, the interior of the brain should next claim attention. The examination should be made in such a way as to cause as little disturbance as possible of the relations of parts by the incisions, and to allow, if desired, that the brain be brought together again after the autopsy and preserved as a whole. This could be done so as to submit every cavity, canal, part, and structure to comparatively minute exploration. Some cerebrotomists, as Bitot, without stopping to investigate particularly the various cavities and subdivisions, at once proceed to divide the brain into blocks by large incisions made at carefully selected points.

The advantages of each of the three forms of sections—vertical transverse, vertical antero-posterior, and horizontal—were pointed out. The vertical transverse sections are the most generally useful. What are known as the middle transverse, mesolobar, or cortico-central zones are most important to understand. These comprise all the cerebral mass situated between the anterior and posterior extremities of the corpus callosum. Bitot describes and figures seven of these zones. Sections and diagrams were exhibited by Dr. Mills, and the places and methods of making these sections were explained.

The particular convolutions, and the regions of the ganglia, cerebrum ovale, capsules, etc., traversed by these sections were shown. The ganglio-insular region was particularly described. This region includes a large portion of the island of Reil, of the optic and striate ganglia, of the external and internal capsules, and of the external wall. The importance of having at command a fixed nomenclature for the various planes and regions was dwelt upon. Following the method of Bitot, the surfaces exposed by the sections were divided into a superior, inferior, and middle division, and these were studied. A diagram representing the relations of the middle portion of the brain to cranium was shown and explained.

Dr. Mills said that he preferred to open the brain so as to expose its ventricles, horns, and parts, and examine each as nearly as possible in its integrity. By his methods, such structures as the corpus callosum, septum lucidum, tænia semicircularis, velum interpositum, choroid plexus, fornix, foramen of Munro, pineal gland and its peduncles, etc., could be, each in turn, investigated for lesions.

After the cavities and horns had been exposed by proper incisions, methodical cerebrotomy, as advised by Charcot and Pitré, or Bitot, could be practised, the cuts being made from within outwards, but not quite through the brain, so that the whole mass could be drawn together again after the cut surfaces had been examined.

Dr. Mills described three of the best methods of opening the brain;

1. At the base, by taking as guides certain fissures and other anatomical landmarks.

2. From the upper surface, by incisions through each side of the corpus callosum, or along the lower borders of the calloso-marginal fissures.

3. By dividing the brain into two symmetrical halves by a careful median section. This should only be done after the parts in the median line had been previously explored.

DR. SHAKESPEARE said that he would like the author to state why he prefers to open the brain from the base rather than from above. Dr. Shakespeare thought that by opening from above, the floor of the lateral ventricles would be better explored, which contain the large ganglia of the brain, and a better topographical view would be obtained.

The most usual cause for which the brain is examined is apoplexy. In these examinations it is necessary that very thin sections shall be made so that all parts can be carefully examined. Dr. Mills has already pointed out the desirability of making these sections in such a manner that none shall be detached, so that when the examination is over all can be readily replaced still leaving the brain practically in one piece. I believe that these two objects can better be obtained by making the examination from above as taught by Prof. Orth (*Compendium der Pathologisch Anatomischen Diagnostik*) than by making it from below. The only part capable of holding the sections together is the cortex with its adherent vessels. Prof. Orth advises making a longitudinal section towards the cortex on a level with the corpus callosum. This section is made deep enough to cut the cortical convolutions half through. This leaves enough tissue to keep the part attached. The anterior horn, the ventricles, and posterior horn are laid open by a second incision. Transverse cuts as thin as desired are then made in the side-pieces. These cuts go half way through the cortex. The large ganglia are then sliced transversely, beginning at the front and going backwards. These are also made to go half way through the cortical substance of the base and so on. The examination being finished the parts can all be folded together like the leaves of a book, not a single piece having been detached. The only way I can see of making thin sections of every part of the brain by the other method is to divide it into two lateral halves, and then making your sections towards the cortex, for if the sections be made directly across the brain the parts in front of the corpus callosum and behind the peduncles will be entirely detached.

Another objection is that seven sections are too few, and if it is desired to have more, it will be a difficult task to hold the already cut sections in one hand and split them with the knife held in the other.

DR. BARTHOLOW preferred to open the brain from above for similar reasons to those assigned by Dr. Shakespeare.

Dr. Eskridge expressed a preference for the older method.

Dr. Mills then closed the debate by reiterating and amplifying the arguments contained in his paper.

MEDICAL ASSOCIATION OF CENTRAL NEW YORK.

Sixteenth Annual Meeting, held at Syracuse, May 15, 1883.

(Specially reported for The Medical News.)

The Sixteenth Annual Meeting of the Medical Association of Central New York was held at Syracuse, May 15, 1883, the President, **Dr. Theodore Dimon**, of Auburn, in the Chair.

The **President** then delivered

THE ANNUAL ADDRESS,

and took for his subject, "Is Medicine a Science?" He explained the difference between fixed or certain science, and theoretical or hypothetical science. He claimed that medicine is a theoretic science, and reviewed its progress from its establishment in Greece by the Asclepiadæ to the present time.

Dr. A. Clifford Mercer, of Syracuse, exhibited specimens of the

BACILLUS TUBERCULOSIS,

and made some remarks on the subject.

The *bacilli* shown were made evident by the following process: From a cup containing the sputa of a tubercular patient a small portion was removed by means of forceps and placed upon a thin piece of glass, such as is commonly used by the microscopist to cover his specimens. A second cover-glass pressed down upon the sputum, and then removed, caused the sputum to lie in a thin layer upon the first cover-glass. This first cover-glass, with its layer of sputum, was then thoroughly dried and slightly heated over the flame of a Bunsen burner to coagulate the sputum and fix it to the glass supporter for subsequent treatment. The sputum with its supporter was dropped into a watch-glass containing a solution of magenta in water and alcohol, rendered slightly alkaline by caustic potash, and was allowed to remain in this staining-bath fifteen minutes. It was then taken out, washed under a small stream of soft water to remove the excess of magenta and dropped into a watch-glass of diluted nitric acid to dissolve out the last remnant of magenta stain from every object in the sputum excepting the *bacilli tuberculosis.* It was again washed under the soft-water tap and then dropped into a neutral bath of aniline violet for fifteen minutes to tint the objects bleached of their magenta stain and thus cause the magenta-stained *bacilli* to show more plainly. It was then put successively into baths of ordinary alcohol and absolute alcohol, was dried, carefully flooded with a drop of oil of cloves and finally dropped sputum-side down upon a drop of Canada balsam on the centre of a microscopist's glass slip, three inches by one inch. After the Canada balsam had become hard, a ring of shellac dissolved in alcohol was applied about the edge of the cover-glass to prevent the oil of cedar, used later in examining the specimens under the microscope, penetrating beneath the cover-glass and destroying the specimens.

The foregoing process is partly that used by Koch, of Berlin, the original discoverer of the *bacilli tuberculosis*, and partly that modification of the Koch-Ehrlich process used by Gibbes, of London. This mixed process has, happily given excellent results, but was only ventured upon because in Syracuse it is not possible as yet to obtain all the necessities for the Gibbes' process, which is generally thought to give the best results.

Dr. Van De Warker, of Syracuse, reported a case of *Cancer of the Uterus*, and exhibited specimens.

Dr. F. A. Mandeville, of Rochester, read a paper on

APHONIA.

Cases due to laryngeal catarrh or over-exertion of the voice usually yield quite readily, he said, to treatment, which should consist in complete functional rest, the application of astringents and sedatives to the larynx, and of electricity direct to the muscles, effected by means of Mackenzie's electrodes, under guidance of the laryngeal mirror. Cases due to pressure by enlarged glands should be treated by counter-irritants externally and alteratives internally. The galvanic current sometimes proves of signal value in these cases.

Aphonia due to anæmia yields readily to general treatment. In hysterical cases, the methodical exercise of the voice, mechanical irritation of the mucous membrane of the vocal cords, or the application of the galvano-faradic current direct to the vocal cords was recommended. The results from this latter procedure are sometimes very gratifying, as often a single application of electricity to the vocal cords will restore a voice that has been lost for months or years. The relief is not always permanent from a single application; but the continuation of this treatment every two or three days will effect a cure. Hypodermic injections of strychnine, in doses of $\frac{1}{64}$th of a grain to commence with, and increased as necessity requires, are also often followed by good results. They should be repeated every three or four days.

For organic aphonia, no definite plan of treatment can be laid down. Electricity is often beneficial even in incurable cases. Constitutional treatment depends upon the nature and origin of the disease. Tracheotomy is indicated when stenosis of the glottis exists, or is imminent, as in cases of paralysis of the abductors.

Dr. F. M. Hamlin, of Auburn, read a paper on

MICROSCOPIC EXAMINATION OF SEMINAL STAINS.

He stated that after trying the different methods suggested by various authorities, he simply soaked the cloth on which the semen had dried in water, when the spermatozoa could be pressed out and examined.

Dr. Wm. F. Sheehan, of Rochester, read an interesting paper on *Chickenpox in the Adult*. He referred to the difficulty in some cases in diagnosticating varicella from variola, and he reported a number of cases of mistaken diagnosis. He claimed that one source of error was the fact that many writers of authority stated that varicella was a disease exclusively of childhood.

Dr. C. O. Baker, of Auburn, read a paper on *Restoration of the Peritoneum.*

Dr. J. P. Creveling, of Auburn, read a paper on *Sarcoma and Lympho-sarcoma of the Neck and Tonsils.*

Dr. J. O. Roe, of Rochester, also read a paper on the same subject.

Dr. Chas. S. Starr, of Rochester, reported a case of *Pyonephritis*, which he saw under Dr. Billroth's care in Vienna.

Dr. W. H. Brown, of Syracuse, presented a patient from whose right eye he had removed a piece of iron by a magnet.

Dr. Dimon, Chairman of the Committee appointed at the last meeting on the care of the insane, presented their report, which was signed by the committee, **Drs. Dimon, Button**, and **Herriman**, and it was unanimously adopted.

DR. W. S. ELY, of Rochester, reported an interesting case of *Post-partum Hematocele.*

DR. CALVIN, of Clyde, reported a

CASE OF TAPEWORM,

in which he succeeded in expelling the parasite by male fern, after having tried the pumpkin seed in vain.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—DR. CHARLES S. STARR, of Rochester.

First Vice-President.—DR. J. P. CREVELING, of Auburn.

Second Vice-President.—DR. ELY VAN DE WARKER, of Syracuse.

Secretary (three years).—DR. J. N. ARNOLD, of Clyde.

Treasurer (three years).—DR. ALFRED MERCER, of Syracuse.

Censor to Medical Department of the Syracuse University.—DR. RICHARD M. MOORE, of Rochester.

The Society then adjourned.

CORRESPONDENCE.

LETTER FROM PRAGUE.

The Hygienic Exhibition at Berlin—Prague from a Pathological Standpoint—Sword-swallowing and its Pathological Results.

AFTER a pleasant sea-voyage and ten days' travelling in Germany, I reached this place just three weeks ago. I was, of course, particularly interested in the hygienic exposition in Berlin, and spent three most delightful days there, chiefly in the pavilion of the "Gesundheitsamt," *i. e.*, health office of Berlin. All of the apparatus used by Koch in his investigations was exhibited, as well as pure cultivations of every known species of bacteria. The methods of work, etc., were fully explained by one of the assistants from the office, detailed there for that purpose. The macroscopic differences—differences in mode of growth, in color, in effect on the gelatine, and in the various bacteria—could be well studied in the test-tubes in which they were exhibited, these macroscopic differences being in many cases more valuable as a means of differential diagnosis than the microscopic, just as, in many cases, plants will present more differences when growing in a mass than will be seen on closer analysis of the individuals. Of course this collection included cultures of the tubercle-bacillus, as well as of the last bacillus that has been made known to us through this office—viz., that causing the "Rotz" farcy. This form presents both macro- and microscopically much similarity to the tubercle-bacillus, as does indeed the farcy nodule to the tubercle, but there are sufficient points to make a diagnosis tolerably easy.

In another room of the pavilion, charts were exhibited which showed at a glance the mortality for each year of life in the different districts in Germany. The mortality was represented by the different shades of red, a light pink being the most favorable, and from this the color deepened to very dark red, Bavaria being mostly painted so dark that but little of the red tinge could be seen. Munich, where one would think the beer alone would offer sufficient inducement to the people to stay there forever, to say nothing of other inducements, such as music and art, seemed to head the mortality list.

Another room showed the methods used in analyzing water—not as to its chemical constituents, but as to the number and nature of the germs contained in it.

In the Austrian department were a series of tables showing the comparative mortality of the zymotic diseases in Vienna, before and after the introduction of the Hochquelle water, in 1873. The decrease brought about in the number of cases of diphtheria and typhoid was most striking.

It makes an American always feel a little badly to see in another country such an institution as this Berlin health office; to think of the great and good work which is being done there in the cause of science and humanity (for they always go together), while we, although ready to reap the results of all work done elsewhere, contribute so little to the general cause. Well, quite a number of us pride ourselves on being too practical to devote our time to such work, but looking at it in its narrowest view—strictly a monetary one—it pays. The decrease in the number of cases of anthrax in cattle, due to the discovery of the etiology of the disease and the conditions of its spread, has been more than sufficient to pay all costs of conducting the institution, for which the German Government gives nearly $50,000 annually.

From a pathological aspect, the fine old city of Prague is perfect. True, people with æsthetic noses might feel badly in some of the streets, and capricious stomachs might rebel at some of the food one has to partake of, but for the study of pathological anatomy it is perfect. A population of 240,000, and last week 214 deaths. Typhoid fever, dysentery, and other intestinal affections make up a large part of the autopsies. The typhoid here, as seen in the Pathological Institute, is almost always perfectly typical, and indeed I often think if post-mortems were made more carefully and extensively with us, a good many of those wonderful atypical cases of typhoid, typho-malaria, etc., could be cleared up. Possibly, too, we would then have more cases of acute tuberculosis, and not so much typhoid.

There is no typhus here as yet, but in the present health relations of the place—the poverty, filth, and general malnutrition of the lower classes—it may pretty safely be reckoned on in the winter. The great prevalence of typhoid is probably due to the bad water, that from several wells being in fact known to be infectious.

The old adage that it never rains but it pours seems often well illustrated in medicine. Sword-swallowers are known to be comparatively rare everywhere, and autopsies on them in consequence of injuries received while pursuing their lawful occupation, are still rarer; yet last week we had two of them in the Institute. One especially was a very remarkable case. The subject was a young man of eighteen, tolerably well nourished. The sword he used had been long in the family—was in fact a sort of *sabre de mon peré*—and for a number of years had been used in this peaceful manner. This constant use had weakened the weapon, so that when, after swallowing it, the young man made his usual stiff bow to the public, it broke, the handle and several inches dropped out, the rest remained. The father, who was also a renowned artist in this line of work, immediately thrust another sword down the boy's throat, to see what had become of the first, and to facilitate its passage into the stomach in case it had become lodged in the œsophagus. After this, the boy was given violent emetics, then swung up by the heels, but to no purpose, and finally was sent into the hospital. By palpation, the piece of sword could be felt in the stomach, but it was not possible in any way to get it lengthways between the hands. Prof. Gussenbauer operated, and drew out a piece of steel 27 centimetres (10½ inches) in length. After a few days, the boy was post-mortemed, and it was found that the operation wound had completely healed, but that a circumscribed peritonitis had taken its origin from another part of the stomach. Here was a perforation, and a dark line extended from this across the stomach and up the œsophagus to a laceration. The explanation was easy; the piece was too long to pass entirely into the stomach; so one end had rested there, the other remaining in the œsophagus. As the œsophageal end was jagged, it could not move up, and in consequence of the violent emetics, and the turning up side down, lacerations had been made at the two points.

The other case was more simple. This man, an uncle or some relation of the first case, lacerated the pharyngeal wall; a violent phlegmonous inflammation of the surrounding parts was set up, and his death was caused by this in a few days.

It remains to be seen whether this interesting family will contribute anything more to our knowledge of the pathological possibilities of sword-swallowing. I only mention these two instructive cases on account of the practical points they involve.

W. T. C.

Prague, June 14, 1883.

A SUPPLE TONGUE.

To the Editor of The Medical News.

Sir: Last winter, a gentleman, who happened in my office with one of my patients, asked me what I thought of the possibility of passing the tip of the tongue behind the palate into the vault of the pharynx. I told him I thought it might be possible, but extraordinary, whereupon he proceeded to demonstrate it by slowly turning the tip of the tongue backward and carrying it behind the edge of the palate to the vault of the pharynx. He said that he had first attempted the feat for the purpose of dislodging collections of mucus from the post-nasal space. It required considerable practice, and at one time, while learning it, he had been seized with a spasm of the muscles of the tongue that nearly choked him. He now accomplishes it as easily as the protruding of the tongue from the mouth, and he has acquired so much dexterity that he can tell accurately the condition of the turbinated bones as to swelling.

The catarrhal condition which first caused him to practise this method of freeing the parts has entirely disappeared, and now nothing abnormal can be seen either in the pharynx, palate, or tongue, excepting some swelling of the turbinated bones at their posterior ends. Respectfully yours,

E. Fletcher Ingals, M.D.

Chicago, June 25, 1883.

NEWS ITEMS.

BALTIMORE.

(*From our Special Correspondent.*)

The Chemical Laboratory of the Johns Hopkins University has recently been completed, and formally opened by Prof Remsen. The building covers a space of about 100 x 50 feet, and consists of three stories and a basement. It is constructed of pressed brick and Cheat River bluestone, and while making no pretensions to architectural effect is nevertheless a handsome and substantial-looking edifice. In the basement are the storerooms for apparatus, two large rooms fitted up for assaying and other furnace-work, and rooms intended to be used for operations upon a large scale. There are also two large steam-boilers which heat the chemical laboratory and the adjoining biological laboratory, which is now in course of erection, and will shortly be completed.

The main entrance to the laboratory is upon the first floor, and adjoining the entrance are, on the left the "gas-analysis" and "photometric" rooms, and on the right, "laboratory A," a large room 30 x 32 feet, supplied with desks for 40 "minor-course" students; each desk is supplied with gas and water, shelves for reagent bottles, and drawers and a cupboard for apparatus, etc.

The gas-analysis room is, as its name implies, designed for operations with gases. It is a well-lighted room with a very carefully and tightly laid floor, so constructed that if any mercury (large quantities are employed in gas analysis) be spilled upon the floor, it runs into a receptacle provided for the purpose, and is not lost. The photometric room is designed for photometric, spectroscopic, or other work requiring a dark room; the windows are fitted with blinds, by means of which the room can be rendered perfectly dark, and the walls and ceiling are blackened to prevent reflection from them.

Adjoining the photometric room is the apparatus office, from which students obtain their apparatus, giving the custodian a receipt for it; then comes the "balance-room," and laboratory B, 30 x 42 feet, with desks for thirty "major-course" or second-year students. The desks in this room are similar to but somewhat larger than those in "laboratory A." The private laboratory and office of the sub-director, Dr. H. N. Morse, adjoin, and, with a store-room for chemicals, constitute the remaining rooms upon the first floor.

Upon the second floor is the main "lecture-room A," seating about fifty (27 x 30), behind which is the preparation-room, used in getting ready the lecture experiments. Next to the lecture-room is the library, consisting entirely of works upon chemistry and mineralogy, and containing all the principal journals of these sciences in the world. In the front of the building, and extending across its entire breadth, is "laboratory C," or the "research-room." This is a very handsome room, 16 x 55 feet, with walls of enamelled brick, and is capable of accommodating comfortably about twenty students. It is exclusively occupied by the "Fellows," and other advanced students, who are engaged in original research in the science of chemistry. Adjoining and communicating are the handsome private office and private laboratory of the Director, Prof. Ira Remsen.

The remaining rooms upon this floor are a "balance-room" for the use of the occupants of "laboratory C" and the "combustion-room."

Upon the third floor are "lecture-room B," seating about twenty, employed for special courses of lectures on chemistry, and "lecture-room C," devoted to mineralogy and provided with desks for blowpipe-work; both these rooms have adjoining preparation-rooms. The rest of this floor is taken up with the large "museum" or collection-room, 30 x 55 feet, containing the mineralogical collection and the collection of chemicals used in illustrating the lectures.

Two preparation-rooms communicate with the museum, and are used in preparing specimens of minerals or chemicals to be placed in the collection.

A noticeable feature of all the rooms in the laboratory is the size and number of the windows, and the height of the ceilings, insuring abundance of light and fresh air; the ventilating arrangements are also very perfect and efficient.

The laboratory is very fully provided with all the latest forms of apparatus, and, in short, in completeness and convenience it is probably second to no other in the world.

PHILADELPHIA.

A Porro Operation.—Dr. W. H. Parrish performed a Porro-Müller operation on a dwarf at the Philadelphia

Hospital on June 28th. The case terminated unfavorably on the third day.

BERLIN.

(*From our Special Correspondent.*)

The Hygienic Exhibition.—At the opening ceremony of the "Ausstellung für Hygiene und Rettungswessen," which had been so sadly destroyed by fire last year, H. I. H., the Crown Prince of Germany was present in the name of the Empress Augusta, the lady patroness of the exhibition. Surgeon-General W. Roth, of Dresden, is one of the presidents. The enormous exertions of the committee to repair last year's losses have been crowned by full success—thanks to the active support of private individuals as well as of local and State authorities.

The great attraction for members of the profession is the "Pavilion of the Board of Health," representing two laboratories fitted with all implements for researches on infectious diseases and disinfection on the one hand, and on adulteration of food on the other. In the former are seen the different kinds of sterilizing apparatuses, the thermostate after d'Arsonval, and Leitz's microphotographic apparatus. There are exhibited, besides, specimens of all micro-organisms till now bred in pure cultures, from the common penicilium up to the bacilli of anthrax, tuberculosis, and farcy. Here Dr. Robert Koch himself and his assistants are demonstrating in the most liberal manner the principles of their methods as described in the "Communications of the Board of Health." Even quite new, and yet unpublished, results are freely laid before the visitors, for instance the discoveries recently made in the process of *milk-coagulation*, than which none can better, and in a more simple way, illustrate the principles and prospects of pure culture experiments.

It is well known, that sterilized milk in a test-tube, if protected against organic germs by a cotton-wool cover, will rest unchanged for months. The power of coagulation, therefore, must be due to the micro-organisms prevailing in this fluid before sterilization, but it was quite uncertain to which of them this power was to be ascribed. Now, Koch's method has soon settled the question. Pure cultures of the "Oidium lactis" do *not* change the sterilized milk in any way, and not more so a micrococcus very common in ordinary milk. On the contrary, a *bacillus* producing lactic acid by its development, instantaneously effects regular coagulation, another bacillus (producing butyric acid) coagulates more irregularly. This discovery may become a clue for the etiology of infant diarrhœa. The methods for testing water, air, and soil, already described in the *Mittheilungen*, are likewise much improved since, and will soon become equivalent to the merely chemical methods.

A second object, which deserves the full attention and the profound study of all sanitarians, is a collective exhibition of thirty-six town municipalities, showing by maps, drawings, and models, the different sanitary arrangements made in every place, as for sewage, water-supply, school and hospital building, street pavement, etc. The large communities of Berlin, Hamburg, Frankfort, and Vienna, are naturally excelling among their sisters.

The hygiene of prisoners is illustrated by instructive models, contributed by the Prussian Ministry for Justice.

Among the conveyances for the transport of sick and wounded, the Prussian and Bavarian hospital trains are of special importance for our warfaring country. A new hospital tent is exhibited by the Prussian War Department. Prof. Esmarch in his field companion destined for the Serbian army, has adopted the tablet form for the medicaments to be carried in the field.

Mr. Siemens, of Dresden, has erected in the exhibition territory his cremation-stove in full size.

Surgical, optical, physiological, and self-registering meteorological instruments, are abundantly exhibited.

The catalogue of the library contains in the average 2500 books, maps and diagrams, and 180 periodicals; due stress has been laid upon statistics.

In the evenings, the place is illuminated by all different sorts of electric and gaslight.

The whole will be of great benefit for the prosperous development of a science so eminently practical and so much depending upon the intelligent understanding of the population as hygiene.

The exhibition is intended to be kept open until the middle of October.

Harvard Medical School.—At the annual commencement of Harvard University, held on June 27th, the degree of M.D. was conferred on seventy candidates.

The Kentucky School of Medicine.—At the Twenty-eighth Annual Commencement of this School held at Louisville, on June 26th, the degree of M.D. was conferred on fifty candidates. The valedictory address was delivered by Prof. J. M. Matthews.

A Banquet to Professor Villemin.—Prof. Verneuil, in the belief that during the now prevalent discussions on the question of the communicability of tuberculosis the claims of Prof. Villemin, of the Val-de-Grace, have been too much overlooked, especially by foreigners, organized a protesting banquet at the Café Riche. It was largely attended by members of the Faculté de Médecine and medical officers of the army and navy, and several eloquent addresses were delivered. In the toast of the evening, Prof. Villemin's claims as the discoverer of the inoculability of tubercle by experimental investigations were warmly and successfully vindicated. As might be expected on such an occasion, these claims were carried somewhat too far when it was maintained that all the recent discoveries relating to the parasitic nature of the disease are only the natural and necessary results of Prof. Villemin's and M. Pasteur's researches.—*Medical Times and Gaz.*, June 9, 1883.

Antivivisection.—On the 22d of May, while engaged in demonstrating the fact that analgesia without loss of general sensibility could be produced in the larynx, M. Brown-Séquard was attacked by a young woman, who struck him with her umbrella. Her defence was, that the experimenter intended to cut the vocal cords of the monkey so as to prevent its crying out. This accident has produced a strong "contra-antivivisection" feeling, and on May 31st, M. Brown-Séquard lectured on "The Utility of Vivisection" to a large and enthusiastic mixed audience.

New Medical Journal.—*Gazzetta degli Ospitali* announces the appearance of La Condotta Medico-Chirurgica Itialiana, but neglects to give the place of publication.

Smallpox in Bombay, India.—The epidemic declared itself early in January of this year. During the week which ended on the 23d of that month there were 32 deaths from the disease recorded within the municipal limits, and in spite of the efforts of the Health Department to check it, the mortality rose steadily week by week until it reached its maximum of 137 deaths during the week which ended March 6th. The weekly death-list increased from 32 to 71, 88, 94, and 107 to its maximum. During the week which ended March 13th there were 131 deaths recorded; 123, 93, and 89 in the three following weeks, after which there was an increase to 101. The disease then began to decrease rapidly, the weekly mortality falling from the last-mentioned number to 66, 49, 46, and 21 during the week which ended May 8th. The deaths were scattered over all the districts of the town. With the exception of one or two European sailors, the victims were low-caste Hindus, and to a lesser extent Mahomedans. Smallpox prevails with much virulence at many other points in the Bombay Presidency.

PORRO OPERATION.—DR. BONORA performed the Porro operation for grave pelvic deformity, on May 4. A telegram about ten days afterward stated that the patient was doing well. Pulse 91, temperature 98.6°. The operation was completed in forty-five minutes.

RESISTANCE OF THE BLACK RACE TO SCARLET-FEVER POISON.—Among the *news items* of the issue of this journal for May 19, some figures were given, showing that our colored population do not succumb to the diphtheritic poison so readily as their white brethren. A similar resistance appears to be manifested by them against the allied scarlatinal poison. Statistical returns in this country are somewhat fragmentary; but we succeeded in obtaining the needful data for the year 1881 with respect to fourteen of our towns having mixed populations. They were Wilmington, Del.; District of Columbia, Norfolk and Petersburg, Va.; Wilmington, N.C.; Charleston, S.C.; Atlanta, Ga.; Natchez, Miss.; New Orleans and Shreveport, La.; Nashville and Memphis, Tenn.; Louisville, Ky., and St. Louis, Mo. The mortality returns of several other cities, such as Richmond and Lynchburg, Va., and Savannah and Augusta, Ga., were examined, but they were not embraced in the calculation, as no death from scarlet fever either among the white or colored people appeared on them. These fourteen towns had an aggregate population of 1,156,801, of which 871,886 were whites and 284,915 colored people. The recorded deaths from scarlet fever in this population amounted to 526, of which 85 were deaths of colored and 441 of white persons. Had the colored people died at the rate which prevailed among the whites, 144 deaths would have been recorded instead of 85. In other words, the deaths of the colored people from scarlet fever were to those of the whites as 1 is to 1.7. The figures formerly given as to diphtheria are in the proportion of 1 to 1.5. This smaller death-rate is the more remarkable when we consider the overcrowding and other unsanitary conditions in the habitations of the colored people; their improvidence; the poor nursing given to their sick, and neglect of medical attendance.

HEALTH IN CALIFORNIA.—The *Monthly Circular* for April of the State Health Board gives abstracts of the reports of deaths in twenty-two towns having an aggregate population of 115,980. The reports from San Francisco and Oakland were not received in time for tabulation. The mortality-rate in the twenty-two towns was equal to 14.89 per 1,000 annually. In Sacramento the rate was 15.99. Consumption caused 22.9 per cent. of the total mortality. This is a much larger percentage than is given by the cities in the Eastern States—larger even than the percentage given by the colored people of the Southern towns. But this is owing not to any greater prevalence or mortality of consumption on the Pacific coast, but to the lesser mortality from other diseases. Consumption stands out as a more prominent figure in the mortality lists. Acute pulmonary affections caused 15.3 per cent., and typhoid fever 4.2 per cent. A single death is attributed to diphtheria, reported from Sacramento; one to croup, and one to scarlet fever, both from Los Angeles; two to whooping-cough, one from Sacramento, and the other from Stockton; two to smallpox, from Nevada City, and two to measles in San Bernardino. Smallpox at Napa and Nevada City has been kept under control. This disease has also appeared in a family at Visalia, six cases, one of which was fatal; and in Tulare County, about twelve miles from Visalia, eight cases and one death, all in one family. Preventive measures have been adopted.

HEALTH IN MICHIGAN.—Reports to the State Board of Health, for the week ending June 23, 1883, indicate that diarrhœa has considerably increased, that remittent fever, whooping-cough, bronchitis, and cholera morbus have increased, and that measles has decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending June 23d, and since, at thirteen places, scarlet fever at twenty places, and measles at twenty-two places. Smallpox in Kalamazoo Township, June 23d.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 25 TO JULY 2, 1883.

HEGER, A., *Major and Surgeon.*—Relieved from the further operation of paragraph 9, S. O. 55. c. s., Department of Texas, and will return to his station, Fort Clark, Texas.—*Par. 2, S. O. 69, Department of Texas, June* 25, 1883.

SMART, CHARLES, *Major and Surgeon.*—Assigned to duty in the Office of the Surgeon-General, U. S. Army, and in addition to his duties in the Surgeon-General's Office, will continue to serve as a member of the National Board of Health.—*Par. 8, S. O. 147, A. G. O., June* 27, 1883.

HAVARD, VALERY, *Captain and Assistant Surgeon.*—Assigned to duty with expedition to complete the survey of the country west of the Rio Pecos, Texas.—*Par. 8, S. O. 68, Department of Texas, June* 22, 1883.

WINNE, CHARLES K., *Captain and Assistant Surgeon.*—Assigned to duty as Post Surgeon at Fort Winfield Scott, California. —*Par. 1, S. O. 69, Department of California, June* 19. 1883.

WORTHINGTON, JAMES C., *Captain and Assistant Surgeon.*—Assigned to duty at Cantonment, on the Uncompahgre, Colorado. —*Par. 4, S. O. 128, Department of the Missouri, June* 21. 1883.

EVERTS, EDWARD, *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort Coeur d' Alêne, and assigned to duty as Post Surgeon at Fort Lapwai, Idaho.—*S. O. 81, Department of the Columbia, June* 14, 1883.

STRONG, NORTON, *First Lieutenant and Assistant Surgeon.*—Relieved from operation of Par. 2, S. O. 42, c. s., Department of the Platte, and assigned to duty with battalion infantry now on duty between Forts Thornburgh and Bridger, Wyoming.—*Par. 2, S. O. 83, Department of the Platte, June*, 21, 1883.

To be Assistant Surgeons, with the rank of Captain, after five years' service, in accordance with Act of June 23, 1874:

Assistant Surgeon VICTOR BIART, June 6, 1883.
Assistant Surgeon WILLIAM W. GRAY, June 6, 1883.
Assistant Surgeon LOUIS BRECHEMIN, June 6, 1883.
Assistant Surgeon LOUIS A LA GARDE, June 6, 1883.
Assistant Surgeon JUNIUS L. POWELL, June 6, 1883.

—*A. G. O., June* 25, 1883.

ORIGINAL LECTURES.

POPLITEAL ANEURISM.

A Clinical Lecture, delivered in the Hospital of the University of Pennsylvania.

BY JOHN ASHHURST, JR., M.D.,
PROFESSOR OF CLINICAL SURGERY.

(Reported by LOUIS J. LAUTENBACH, M.D.)

GENTLEMEN: The case which I bring before you to-day is one which is interesting in relation to diagnosis as well as in regard to treatment. The case is one of aneurism of the popliteal artery.

The patient's history is that in 1878, somewhat over four years ago, he was shot in the calf of the left leg, the ball of a small pistol entering and passing upward. The scar of the wound is seen indistinctly; the wound was apparently trivial. From two to two and a half years after the injury, the patient noticed a small lump, which pulsated. The pulsation increased for some months, but he says that it is now not as marked as it has been.

The growth of the tumor, until three or four weeks ago, was very gradual, but about that time it began to increase rapidly, until it has attained the size which you now see; it is now about six inches in length and almost as much across.

Let us briefly go over the symptoms of aneurism and the diagnostic points which serve to distinguish it from other tumors. Various definitions of aneurism have been given by different writers; that which I consider the most accurate and, therefore, the most satisfactory, is that an aneurism is a disease of the arteries consisting in a circumscribed dilatation of one or more of the arterial coats. It is not merely a dilatation, since we frequently have general dilatation of the aorta without any aneurism. I do not refer here to the affection termed aneurism by anastomosis, but only to that which is designated by the word *aneurism* used by itself. Some authors have defined an aneurism simply as a tumor containing blood; but, according to this definition, a hæmatocele would be an aneurism.

The tumor here not only *pulsates*, but it has also an *expansive* pulsation, which can be felt by putting the hands on either side of the tumor, and which can be seen by noticing that the hands are pushed apart. If the tumor were a tense bursa, or a fibroid tumor, situated over the popliteal artery, the pulsation would simply be up and down; there would be no lateral pulsation. A very characteristic symptom of aneurism is the *aneurismal bruit*, which is caused by the blood entering the sac of the aneurism; a sound somewhat similar to that which is caused by blowing into a bottle, or which is produced by the rushing of any liquid into a cavity through a small opening. This symptom is not well marked in the present case, and its deficiency is probably due to the fact that the aneurism has reached the stage of what is known as a "diffused aneurism," or, as Mr. Barwell prefers to call it, a "consecutive aneurism." The sac proper of the aneurism has given way, but the condensed tissues outside of the arterial tunics have formed a wall to hold the blood. When the tumor is in this condition the bruit is not as marked as in the early stage. Beside the bruit, we often have present an *aneurismal thrill*. This is not universally present, and it is not found in this case.

There are other very important symptoms connected with the pulsation. Compression of the main artery above the aneurism causes flaccidity of the sac and cessation of the pulsation, but in the case of most tumors the size of the mass will not be diminished. Some vascular tumors will become softer and smaller, but may be distinguished from aneurisms by the way in which the pulsation returns when the pressure is removed. In a case of vascular tumor the pulsation returns gradually, while in aneurism the pulsation immediately returns, and is just as forcible as it was before the main artery was pressed upon.

Another point which is particularly illustrated by an aneurism in this situation is the difference in the degree of pulsation depending on the position of the limb. If there is an abscess or enlarged bursa over the artery in this situation, the pulsation becomes more distinct by straightening the limb, whereas the pulsation becomes less noticeable when the limb is flexed. In popliteal aneurism, however, you diminish the pulsation by straightening the limb, but when the limb is flexed it is more distinct. In nearly all cases of popliteal aneurism you find the pulsation increased by flexion. Another symptom, which is here well marked, is the diminution of pulsation below the tumor. This symptom is explained by the "stand-pipe" or "air-chamber" action of the aneurismal sac, the principle of which is applied in the steam fire engine and in the hydraulic ram. The stroke of the valve or piston corresponds to the stroke of the heart, and would cause, unless some means were taken to prevent it, an intermittent flow corresponding to the interrupted flow of blood when an artery is cut. By the elasticity of the air in the air-chamber the pressure is made constant, and the flow is equalized. Similarly, the elasticity of the aneurismal sac, by equalizing the blood-current, diminishes the pulsation in the distal portion of the artery.

The most important diagnostic marks of popliteal aneurism are then:

1st. Expansive pulsation;

2d. Stoppage of the pulsation and lessened tenseness of the sac by compression of the artery above the tumor;

3d. The suddenness with which the pulsation returns when the pressure is relieved;

4th. The thrill;

5th. The bruit;

6th. The diminution of pulsation below the tumor; and

7th. The increase of pulsation on flexing the limb.

In the large majority of cases where mistakes in diagnosis have been made, they have been due to careless examination. The mistake most commonly made is the mistaking an aneurism for a phlegmonous abscess. Even such an experienced surgeon as Pirogoff made this mistake. He was summoned in great haste to see a patient, whom he found to be suffering with an inflamed swelling of the calf of the leg, the tumor presenting many of the symptoms of an abscess. Pirogoff thrust a knife into the swelling, when arterial blood spurted out and revealed the true nature of the case.

As regards the treatment of popliteal aneurism, where there is an opportunity of employing digital compression this method should, as a rule, be fairly tried. If, however, it is found that in a reasonable length of time no progress is made in the cure of the aneurism, and especially if the compression causes increased venous congestion, it should be abandoned, and the femoral artery tied. As at this hospital we can secure a large number of competent assistants, we nearly always make the attempt to cure popliteal aneurism by digital compression, and usually with success. In this case we began compression over the common femoral and the upper part of the superficial femoral artery at 8 o'clock P.M. last Sunday, and it was kept up almost unintermittently for thirty-six hours, but, I regret to say, without good results, though no harm was done. For a time the congestion of the limb was increased, but during the rest which the patient has had since, this has passed away, and he is pretty much in the same condition in which he was when the compression was begun. Possibly the tumor is a little larger than it was a week ago, but it is probably not larger than it would have been had we adopted no treatment whatever. At first I was very doubtful as to the propriety of attempting compression at all in this case, as the tumor was already a very large one, but concluded to give the patient the benefit of the doubt and make the attempt.

This aneurism, as I have already said, is what is ordinarily called a *diffused* aneurism, but which may be better termed, as it would be by Mr. Barwell, a *consecutive* aneurism. Mr. Barwell calls a diffused aneurism one in which the blood extends widely throughout the tissues of a limb. A consecutive aneurism is one in which the blood, though outside of the arterial walls, is still enclosed in an adventitious sac, formed by the condensation of the tissues surrounding the vessel. Here the blood has escaped from the true sac, but the clinical condition is not that of a diffused aneurism, as the blood is still surrounded by a firm wall of cellular tissue. An aneurism may undergo spontaneous cure, and in our treatment we endeavor to effect a cure in the same way as is done by nature. An aneurism may undergo spontaneous cure by the gradual deposition of laminated coagula, a gradual filling up of the aneurismal sac by the deposit of fibrinous matters—whether derived from the wall of the sac or from the contained blood, is still disputed. The clot is usually said to be derived from the blood in a manner akin to the separation of fibrin by "whipping" blood outside of the body, although some authorities believe the laminated coagulum to be produced by proliferation of the sac-wall. This is the most promising mode of spontaneous cure, and it is that which we attempt to imitate in instrumental and digital compression. It is also that which is aimed at in the Hunterian mode of ligation.

There are two modes of tying the artery on the cardiac side of the aneurism; in Anel's method the ligature is applied immediately above the sac, while in the Hunterian method the ligature is tied at a distance from the sac. The latter method is that which is now universally preferred. It is acknowledged to be the most favorable mode of ligation. After ligation by Anel's method, but one set of collateral vessels undergoes enlargement, namely, that which passes around the aneurismal sac itself. By Hunter's method, we have developed one set of vessels around the seat of ligation and one around the tumor. The process of cure by Hunter's method is not, as many suppose, by an entire arrest of circulation in the sac, but by a diminution in the amount of blood which finds its way into the sac, the slow flow of blood allowing a gradual deposition of coagulum in laminæ. In the case of Anel's method, where the blood is cut off entirely from the aneurismal sac, if coagulation occurs, all the blood coagulates at once, making a dark, soft clot, a "currant-jelly" clot, not as promising a mode of cure as that by the formation of a laminated coagulum. We may have a spontaneous cure effected in this way; but such a clot is apt to be redissolved, or may be followed by suppuration of the sac, which may lead to a fatal result. Moreover, when we have a soft clot formed in an aneurism, there is always danger of a fragment becoming detached and causing embolism of a branch beyond the sac, an occurrence which, if it may occasionally prove beneficial, is more often the cause of death. The cure by embolism is attempted in the mode of treatment by manipulation introduced by Sir William Fergusson.

Besides the two modes of ligating the artery on the proximal side of the aneurism, there are two methods of ligation on the distal side of the sac, known respectively as Brasdor's and Wardrop's operations. In Brasdor's method, the whole current of blood on the distal side of the sac is arrested; in Wardrop's operation, the entire circulation through the sac is not arrested, but the amount of blood is limited by tying one or more branches of the diseased artery. Thus, the distal ligation of the carotid for carotid aneurism would be an example of Brasdor's operation; but the ligation of the same vessel for innominate aneurism would be an illustration of Wardrop's. The cure in Wardrop's operation is effected by the gradual deposition of fibrin, just as in the Hunterian method. If we were to tie all the vessels below the sac, we should cut off the entire circulation, and we should be apt to have a soft, currant-jelly coagulum.

In enumerating the principal methods of ligation, I must not omit what is known as the "old operation," or the "operation of Antyllus," though it is really not the operation which Antyllus actually performed. His plan was to tie the artery both above and below the sac, and then cut the aneurism entirely away. As performed at present, the operation consists merely in laying open the sac, and applying ligatures above and below. This operation, which was successfully practised in a number of cases by the late Prof. Syme, is well adapted to cases of traumatic aneurism, but not to those of spontaneous origin. It has been practised on the subclavian, axillary, and gluteal arteries with good results. In one case of iliac aneurism, which was operated on in this way, where Mr. Syme thought he had tied the common iliac, post-mortem examination showed that only the external iliac had been tied. This method is not suited for cases of spontaneous aneurism, as there is apt in these to be disease of the artery in the vicinity of the sac. The circulation is controlled by digital compression, or a tourniquet above the aneurism, or, where this is not possible, as in cases of axillary aneurism, by Mr. Syme's plan of making an incision above the clavicle, and compressing the artery with the fingers over the first rib. In traumatic aneurism, the extent of impairment of the artery is limited, while in the spontaneous variety the extent to which the arterial walls are diseased is unknown, and may render the application of a ligature in this way impracticable. Thus, if we have a traumatic aneurism in the gluteal region, following a stab, we know that the lesion must be within reach, while in a case of spontaneous aneurism in the same situation, we cannot be certain but that the sac extends into the pelvis. If, in the latter case, we should cut into the aneurism, the patient would probably be destroyed by hemorrhage before the artery could be tied. In non-traumatic aneurism in this situation, therefore, it is better to tie the internal iliac than to resort to the old operation.

Another mode in which spontaneous cure is said to occur, is by suppuration of the sac. Sometimes this results from the irritation occasioned by the introduction of foreign bodies into the sac. The introduction of needles, wire, horsehair, etc., aims to produce coagulation, but may, instead, cause suppuration. The method of the introduction of foreign bodies is not to be advised when other methods are applicable; nor, in my judgment, is the treatment by galvano-puncture to be recommended if there is a possibility of effecting a cure by other measures. The galvano-puncture treatment may have its appropriate place in affording temporary relief in some cases, but it seldom, if ever, ends in permanent recovery; and it is, in itself, not unattended with risk.

In the present case we have, as I have already mentioned, given digital compression a fair trial, but it has failed; and to-day I shall ligate the superficial femoral artery by the Hunterian method at the apex of Scarpa's triangle. The ligation was originally performed by Hunter at a lower point, in what is called the Hunterian canal; but the operation in this situation is more difficult, and possesses no advantage except in special cases. When suppuration of the sac occurs, and it is necessary to ligate the artery for secondary hemorrhage, then we tie it in Hunter's canal; but, when ligation is adopted primarily for popliteal aneurism, we tie the vessel in Scarpa's space. We begin the incision in the upper part of the triangle, carrying it downward for from two to two and a half inches parallel to the sartorius muscle. In tying the artery, the safest rule to follow is to feel for the line of pulsation, which, when it can be recognized, is what surgeons practically rely upon. When the pulsation of the artery cannot be felt, then we must follow certain definite, fixed lines; those given by Mr. Barwell being among the most satisfactory. Having turned the limb outward, one line is taken from the middle of the abdomino-femoral fold to the inmost point of the inner condyle of the femur, and then another line is drawn from the anterior superior spine of the ilium, to the junction of the middle and lower thirds of the thigh. Where these lines meet, the sartorius covers the femoral artery, and the incision is made along the inner border of the muscle, so that this point shall be at the middle of the wound. Dividing the skin and superficial fascia, we can recognize the inner edge of the sartorius through the deep fascia, which is then divided along the border of the muscle; drawing this a little outwards, we must avoid a small vein which is often found in front of the sheath, and then remembering that the artery lies to the outer side and the vein to the inner side, we make a small opening in the sheath and pass the aneurismal needle from within outward. Sometimes when the sheath is opened, there is a tolerably free flow of blood, which may lead the surgeon to fear that the vein has been injured; usually this is not the case, the blood coming from the nutrient vessels of the sheath and stopping when the ligature is tightened. If, however, the flow of blood does not stop, the surgeon should separate the vessel half an inch higher up and apply the ligature at that point.

I am sorry to see this muscular tremor in our patient [when he was brought into the amphitheatre after having been etherized]. I have had experience in these cases, and know that this tremor is a very troublesome complication. Muscular tremor is not a complication of much consequence in amputations, where your incisions are bold, but it is very troublesome, and may even be dangerous in an operation of such delicacy as the ligation of a large artery.

In most cases of arterial ligation the ordinary aneurismal needle, with a single curve, is safer and more satisfactory than any other. I have here an ingenious needle with an eye through the posterior as well as the anterior part of its curve. The posterior eye being threaded, when the point of the needle is passed under the artery, it is caught by another instrument which goes into the anterior eye, and which draws the curve of the needle and the ligature through, after the handle has been unscrewed. Sometimes in using the ordinary needle it is better to pass the needle unarmed, and then have an assistant to thread it afterwards.

While the needle lies below the artery, pressure above arrests the pulsation in the tumor, showing that the artery is in the grasp of the instrument; then having passed the ligature around the artery, we must make sure that we have not anything beside the artery included. Formerly, it was the custom to tie the artery and vein together, but now the artery is tied by itself. I secure the ligature with three knots, then fasten the two ends of the ligature together, and allow them to hang out of the wound.

The pulsation now is arrested, and the tumor is much less tense than it was. The wound is closed with sutures, like any other incised wound, after which the limb is carefully wrapped in cotton, so as to protect it from injury, and to keep it warm. There is slight pulsation in the posterior tibial artery. This is by no means unfavorable. I hope that there is enough collateral circulation already established to prevent gangrene.

[The patient did well after the operation, the ligature coming away at the end of two weeks, and the wound slowly healing. When the patient left the hospital, however, the tumor was still somewhat soft, showing that the contained coagulum was not all as firm as would have been desirable, and that the risk of suppuration of the sac had not, therefore, entirely passed away.]

TRACHEOTOMY IN DIPHTHERITIC AND MEMBRANOUS CROUP.

BY FRANK C. WILSON, M.D.,
OF LOUISVILLE, KY.

(*Read before the Kentucky State Medical Society April 5, 1883.*)

It is not my design to review the literature of this subject, but simply to relate two of the cases in which I have performed tracheotomy, together with some observations as to the best methods of conducting the after-treatment in such cases.

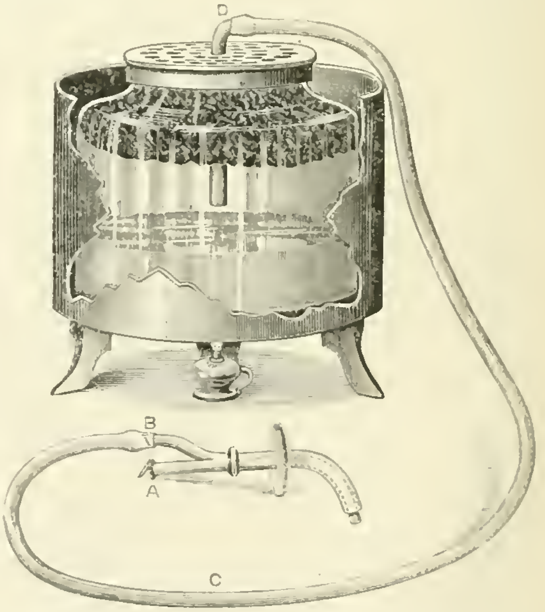
The operation is simple enough, and, if performed with ordinary care, not dangerous.

Case I.—In November, 1881, I was aroused at night to see a little boy, H. M., aged 6 years, who a few days previously had been taken sick with diphtheria involving the nasal passages. A few weeks previously, his little brother had been attended for the same complaint by Dr. Senteny, the family physician, and had so far recovered that it was not thought necessary to visit him.

The parents, recognizing the similarity of the cases, used the same remedies, not deeming it needful to call in the physician until they became alarmed at the development of croupy symptoms. Being in the immediate neighborhood I was hastily called, and at once recognizing the gravity of the case I explained its nature to the anxious parents. I insisted upon having Dr. Senteny sent for at once, and we saw the child several times during the day, one or the other of us remaining with it most of the time. It continued to grow worse in spite of the treatment pursued, which consisted of insufflation of powdered sulphur, and of pepsin, together with the internal administration of quinine, chlorate of potash, tincture of iron, etc.

The obstruction at last became so great that cyanosis supervened and death seemed imminent. I had previously made all necessary preparations for tracheotomy, and having gained the free consent of the parents, proceeded to perform it about one o'clock on the second night. The hemorrhage from the greatly congested vessels of the neck was alarming, and much valuable time was lost in efforts to staunch the flow of blood, before making the incision into the trachea. This was at last accomplished, and the incision into the trachea made, but the coughing and struggling, which the first entrance of air always induces, started with increased violence, the alarming hemorrhage. However, turning the child on one side, no inconvenience was occasioned by the hemorrhage, and the tube being soon introduced, it was easily controlled. The breathing became at once natural and easy, and the cyanosis, before so marked, rapidly disappeared. A large sponge was placed in front of the neck over the tube and kept constantly moist, so as to filter the air and at the same time moisten it. The inner tube required cleansing every four or five hours, and a supply of oxygen was kept constantly on hand, to be used should cyanosis supervene at any time. He was faithfully nursed by his father, and to his watchful care during the after-treatment, no doubt, is greatly due the successful issue of the case. The tube was removed at the end of one week, the opening closed in about twelve or fourteen days, and recovery was complete.

Case II. *Membranous Croup. Tracheotomy on the third day, death on the sixth day.*—F. M., aged 4 years, was out riding, insufficiently clad, and upon reaching home complained of being cold. During the night became hoarse and croupy. I was called the next morning and found considerable obstruction, both in expiration and inspiration, with a clear, ringing, croupy cough. I prescribed turpeth mineral to be used in three-grain doses to produce emesis, whenever necessitated by increasing obstruction; otherwise, in one-half grain doses at intervals of six hours with chlorate of potash in solution at short intervals. The second night he rested a little more comfortably, but there was never entire relief from the croupy cough, and the next night the obstruction became so great as to be alarming. Early in the morning, Thursday, the cyanosis became so marked that I proposed tracheotomy, and having asked for a consultation, Dr. Hewitt was called. Having in the mean time made all preparations, death seeming imminent, I inserted the tube about 9 A.M., there being very little hemorrhage and the membrane not extending below the opening. The breathing immediately became easy and full, and the cyanosis quickly disappeared. The sponge was placed over the tube and the air of the room kept moistened by steam. The case progressed favorably until Friday; about midnight, I noticed that the tube filled with inspissated mucus at short intervals, requiring to be frequently cleansed. After a while even cleansing the inner tube failed to relieve the obstructed breathing, the obstruction being evidently lower down in the trachea and bronchial tubes. Thinking that possibly the dried mucus might have accumulated upon the lower end of the outer tube, that too was removed and cleansed. but still the obstruction remained. A spray of bromide of potash solution was then used with a view of dissolving the mucus. This afforded some, but only temporary, relief. Oxygen was also resorted to with the hope of prolonging life until the membrane in the larynx might separate and be expectorated. I even endeavored to hasten this by passing a sponge probang saturated with a solution of bromide of potash into the larynx, but failed to dislodge the membrane. The tracheal and bronchial obstruction gradually increased until death supervened, just three days after the operation. I remained with this case almost continuously day and night, from the time of the operation until death. Watching it thus closely caused me to realize, as I had never done in my previous cases, the danger of breathing cold, dry, and dusty air directly through the tube into the lungs, and the necessity of imitating as closely as possible the natural air-passages, which filter, warm, and moisten the air before it reaches the lungs. I believe in this case death was due solely to the inspissated mucus accumulating in the trachea and bronchial tubes. To obviate this, and at the same time imitate as nearly as I could the natural passages, I have arranged a respiratory apparatus shown in the figure. It consists, first, of a silver canula provided with two branches, in one of which a valve opens outwards, A, and in the other a valve opens inwards, B. A rubber tube, C, leads from the canula whose valve opens inwards to a jar, D, filled with fine sponge, so arranged that the air has to pass through the sponge which can be kept moist and warm by placing the jar in a vessel of water heated by a lamp. Thus the air breathed will be warm, moist, and free from dust, and can, if desired, be medicated at the



same time. The expired air and the secretions, coughed out through the tube, find exit through the canula whose valve opens outwards. I am firmly convinced that the use of some such arrangement will obviate or greatly lessen the chief danger to which such cases are liable after tracheotomy, and to which is due the great mortality attending the operation. Were the operation rendered thus more successful; we would see fewer cases consigned to their inevitable doom, by the opposition of parents and friends.

Louisville, Ky., April, 1883.

FOUR CASES OF PORRO–CÆSAREAN SECTION

AT THE ALLGEMEINE KRANKENHAUS, OBSTETRICAL DEPARTMENT, VIENNA.

By X. O. WERDER, M.D.,
of Pittsburg, Pa.

As I had the very rare opportunity to see four cases of Cæsarean section performed within two weeks, one in Prof. Gustav Braun's division, and the others in Prof. Carl Braun's clinic, I think it of sufficient interest to give the readers of The Medical News a brief history of the cases and a short description of the operations.

Case I.—April 19th. This woman was about thirty-five years of age, very anæmic, badly nourished, and of a phthisical diathesis. She was delivered of her first child about two years ago, her labor being then very difficult, but normal. During the last one and one-half years she has been suffering with osteomalacia in a very high degree. Labor set in a little prematurely, as she had only passed her eighth lunar month; pains commenced during the night from the 18th to the 19th of April, but she was not admitted to Prof. Gustav Braun's division until about one hour and a half before the operation was commenced. On examination her pelvis was found to be very much contracted, both in the antero-posterior and in the transverse diameters, but especially in the latter, as is usual in such cases, it being caused by the lateral pressure of both lower extremities against the acetabulum in walking. The conjugate diameter measured only four centimetres, instead of thirteen, in a normal pelvis, and the circumference of the pelvis seventy-six centimetres, instead of ninety. The pelvic outlet was extremely small; it was very difficult to introduce two fingers through it. The pubic arch projected like an angle. It is very evident that in such a case there is not only not the slightest chance for a normal delivery, but even a craniotomy cannot be thought of; nothing short of a Cæsarean section can here be considered.

Preparatory to the operation her abdomen was washed and brushed with soap and water and then rubbed off with a five per cent. solution of carbolic acid, and the hair of the pubes shaved off while she was being placed under the influence of an anæsthetic, the usual one in Vienna being a mixture of ether, chloroform, and alcohol. A well-disinfected oilcloth having in its centre an oval opening large enough not to interfere with the operation, was then placed over her abdomen, and through this open space the incision in the linea alba extending from the symphysis pubis to the umbilicus was made, and layer after layer carefully divided until the peritoneum was exposed, which was then opened upon the director. The uterus now filled up the whole incision, the latter was found a little too small, however, for extracting the child; it was, therefore, extended about two inches above the umbilicus. As soon as every bleeding vessel was secured by an artery forceps, the uterus itself was opened with a few bold cuts with the knife, and without regard to the very profuse hemorrhage, the operator thrust his hand into the cavity of the uterus and extracted the child, giving it in charge of an attendant, while the assistants with their hands compressed the edges of the uterine wound, in order to stop the excessive hemorrhage. The uterus was then pulled out of the abdominal wound, an écraseur was passed around it closely to the edge of the incision and this was tightened to its full extent, thus controlling the alarming hemorrhage; about one inch and one-half above the chain of the écraseur the whole uterus was amputated with the knife. In spite of such decided pressure around the stump of the uterus, there was still some blood oozing out; this was stopped by compressing each bleeding point by a Bozeman forceps. The abdominal cavity was now sponged and cleaned out; very little blood had entered it, however, as the abdominal wound had been drawn closely to the sides of the uterus, thus protecting the peritoneum as much as possible. The deep peritoneal sutures were now applied, for which purpose silver wire was used, which was tightened by a small lead-plate and shots, the so-called button suture, over this the superficial suture with simple carbolized silk was made uniting the upper part of the uterine stump to the wound, after it was pressed against the symphysis pubis as much as possible. After the abdominal wound was closed, the pedicle was thoroughly cauterized with the thermo-cautére and then dusted over with iodoform. Iodoform gauze was then tightly packed around the stump still included in the chain of the écraseur, which is to be kept on until the pedicle sloughs off, which generally takes place about the tenth or twelfth day; the rest of the wound was covered very lightly with the same material Over this a piece of silk was placed, on top of this antiseptic cotton and a mackintosh, a large linen bandage reaching all around the body finished the dressing.

The child cried immediately after the extraction, and though not of full term, is thriving pretty well. The mother succumbed to the operation on the end of the third day; the exact cause of death I could not ascertain.

Case II.—April 25th. Prof. Carl Braun's clinic. This woman was a strong, vigorous primipara, twenty-three years of age; at the end of the tenth lunar month of pregnancy. She has been subject to rachitis in her early childhood, and as a consequence of which she has now a pelvis contracted in all its diameters. The conjugate diameter is only 6 cm., instead of 11 in a normal pelvis; the right oblique diameter 5 cm., instead of 11¾. and the left 4 cm. The circumference of the pelvis measures 78 cm., instead of 90; the distance between both anterior superior spinous processes of the ilium 20, instead of 25 cm.; distance between the highest points of both crests of the ilium 23 cm., instead of 28; distance between the trochanters of the femur 28 cm., instead of 32. The fœtus was very well developed and estimated to weigh about 3500 grammes (it actually weighed 3350 grammes). An ordinary fœtus could never be born through such a small pelvis, even after craniotomy, which would even be too small for a fœtus of only 1500 grammes; there was, therefore, no alternative in this case but to perform Cæsarean section. The patient having been under observation for about two weeks, it was preferred to do this a few days before labor was expected, because the pains would not only be a very undesirable complication to the operation, but the damage very likely to be done by them to the cervix by bruising and tearing it, should be avoided if possible.

The operation as performed by Prof. Carl Braun, was very similar to that of Prof. Gustav Braun. The preparatory proceedings in regard to washing and sponging of the abdomen, catheterizing the bladder, etc., were exactly the same, but the incision in the linea alba was made a little higher up in this operation. For, while in Case I., the incision extended down to the symphysis pubis, and only about one and one-half to two inches above the umbilicus, Prof. Carl Braun commenced it about one to two inches above the symphysis and carried it up higher above the umbilicus, so that about two-thirds of the incision were below and one-third above the umbilicus, the reason of this being to prevent any injury being done to the bladder. After the peritoneum was opened and the bleeding vessels controlled, he did not cut into the uterus immediately, but pulled the entire uterine tumor out from the abdominal cavity, protected the intestines with large abdominal sponges, and had the edges of the wound drawn together by an assistant. A long elastic tube was now applied very tightly around the neck of the uterus for the purpose of controlling the enormous bleeding, by which the incisions into the pregnant uterus are followed, the écraseur was also passed around it, but not tightened. These preparations completed, the entire uterus was opened by a few quick incisions, and the living child extracted, while an assistant closed the écraseur tightly around the womb. The amputation of the uterus, the closing and dressing of the wound, and the extra-peritoneal treatment of the pedicle were exactly the same as in the first operation, only with this difference, that the whole stump was united to the abdominal wound, all around it, by a number of sutures, not the upper part of it only, as done by Prof. Gustav Braun.

CASE III.—April 26th. Prof. Carl Braun's clinic. This patient, an idiot, was also a primipara, thirty-two years of age, well nourished, and at the end of the tenth lunar month of pregnancy; she had a rachitic pelvis, deformed and contracted in all its diameters, similar to the previous case, nearly all the measures and diameters being of about the same length.

Conjugate diameter (vera) 6 cm., instead of 11.

Conjugate diameter (diagonalis) 8 cm., instead of 13.

External conjugate 17 cm., instead of 20 cm.

Distance between ant. sup. spinous process of ilium 21 cm.

Distance between highest points of both crests of ilium 25 cm.

Distance between both trochanters of the femur 28 cm.

Circumference of pelvis 80 cm.

The whole pelvis had a kidney-shaped form, it being contracted in the highest degree in its antero-posterior diameter. The child was not as well developed in this case as in the previous one, its weight being estimated to be from 2500 to 2800 grammes. The indications for the Cæsarean section were, of course, just as decided as in Case II. The operation did not differ from the last one, but after cutting off the uterine circulation by an elastic tube drawn tightly around the lower part of the uterus, as was also done in the foregoing case, there was some little delay before the child could be extracted, as a consequence of which the child in utero, being without the mother's nourishing fluid, was forced to respire, and, in so doing, aspirated some of the amniotic fluid. It was, therefore, asphyxiated when it was born, though it made several efforts to breathe and cry, which only served, however, to drive this aspirated fluid still further down into the bronchial tubes, filling them up, and mechanically preventing the air from entering them. In spite of all the care and attention paid to it, it died a few minutes after its birth.

CASE IV.—May 1. Prof. Carl Braun's clinic. This case was very similar to the first one. The woman is forty years of age, suffering with osteomalacia in such a degree that she has not been able to walk for a long time. She generally lies in a horizontal position, with her thighs flexed upon the abdomen. When she entered the obstetrical wards about six weeks ago, she was very badly nourished, and in a very weak condition, but, since then, she has improved very much, because, preparing her for this operation, everything has been done to raise her nutrition, and to bring her system into such a condition as to be able to withstand such a serious operative procedure. She was delivered of a child, with the forceps, about ten years ago, and since then she has had an abortion. This pelvis is contracted most intensely in its transverse or oblique diameters, as in the first case, and the symphysis pubis is again very much elongated and projecting. The oblique diameters, both right and left, are only four cm. instead of eleven and three-fourths; the pelvic inlet is also of the same size. In such cases, of which Prof. Carl Braun has not seen more than about ten in his thirty years' experience, at least where the deformity of the pelvis was so pronounced, he has always performed Cæsarean section, though it has been suggested by some authors that, the bones being so soft, porous, and yielding, an extraction of the fœtus through the pelvic outlet could be made without injury to the mother. This, however, he regards as more than doubtful, and thinks it safer to deliver the child by laparotomy, especially as this operation has lately given such good results.

The operation was performed in the same way as before, but learning from the experience in the last case, the elastic tube was not drawn tightly around the cervix until the operator was ready to make the incision into the uterus, as a consequence of which he extracted a living, crying child. The placenta was inserted just in the line of incision, so that it had to be cut through before the cavity of the uterus was reached; this caused a little more hemorrhage than usual.

Remarks.—It is proper to mention here that all the four operations were performed strictly antiseptically in every respect, though not all of the minutiæ of Lister's dressing were observed. The spray was used in the operating-room before, but not during the operation.

The result of the first operation has been stated above: death ensued on the third day; whether due to the operation, or to her weakened condition and tuberculous diathesis, or both, I could not ascertain. More fortunate was Prof. Carl Braun with his three cases: they are all on the road to recovery. The first case did not have the slightest rise of temperature, and was feeling remarkably well, until the end of the third week, when apparently without the least cause, she was suddenly attacked with phlegmasia alba dolens. The affection is, however, getting better rapidly, and she will, in all probability, be soon restored to health.

The third case, an idiotic girl, as has already been stated, was getting along equally well in every respect, but her suture having been removed on the eighth day, she succeeded, in one of her wild hallucinations, in tearing apart the slightly adherent surfaces of the abdominal wound, so that the whole larger omentum was hanging out of the wound. Prof. Carl Braun returned this into the abdominal cavity, but did not find it advisable to pare the edges of the incision, and to reunite it; he simply drew them together by strips of adhesive plaster, after having it thoroughly disinfected with iodoform. In spite of this very unfortunate accident, Prof. Braun regards her prognosis as a very favorable one, and is of the opinion that the wound will close and heal perfectly by granulation, though it will probably require several months to do so, instead of a few weeks.

The second patient with osteomalacia, the most unpromising case of the four, was the most fortunate after the operation. Her convalescence has not been interrupted at any time by any unfavorable symptom, so that she will soon be able to leave the hospital. The original disease—osteomalacia—does not seem to trouble her very much at present; she can move her lower extremities now with perfect freedom, and does not suffer any pains. She is very happy and satisfied with her condition, and states that she has not felt as well as now since the beginning of pregnancy.

The children are all living and well, except the one mentioned who died immediately after birth.

The operation itself is that recommended by Porro, and known under the name of Porro's operation, who was followed in all these four cases in every particular, if I be not mistaken. The results of Cæsarean section since the introduction of this method here in Vienna have been very good; not more than about thirty per cent., perhaps less, of those who have been operated upon here since have died. A modification of Porro's operation, as suggested by Schrœder and others, was tried in two cases by Prof. Gustav Braun. Instead of cauterizing the stump of the uterus with the Paquelin cautery, and treating it extra-peritoneally, he united the mucous membrane of the pedicle by sutures, so that the wound was entirely closed, and returned it into the abdominal cavity—in other words, he treated it in the same way as is generally done after ovariotomy. The results, however, were disastrous, for both patients died a short time after the operation, and, on the autopsy, the whole abdomen was found full of blood, though the wound of the stump in the last case had been united by over thirty sutures.

These hemorrhages are not hard to explain, if it is considered that the tissues included in these sutures are muscular and contractile, very unlike to the pedicle of ovariotomy, and that, in shrinking, the sutures become loose.

The successful results with which Porro's operation has been accompanied are, in my opinion, very encouraging, and, if not everything deceives me, it will have a brilliant future. I hope that the time is not very far off when it will supersede a very unscientific, unsurgical, and detestable obstetrical operation—craniotomy—at least in all those cases in which a living child is at stake.

Vienna, May 25, 1883.

MEDICAL PROGRESS.

The Functions of the Spleen.—There can be no doubt in the value of the spleen in the process of the formation of blood, but it would be difficult indeed to add anything very novel to what has already been conjectured in this matter. It has long been decided that the spleen is not an organ absolutely essential to life. Some fresh experiments bearing on the subject of the functions of the spleen have been instituted by Prof. Zesas. The spleen was removed from many rabbits, and the animals were afterwards killed at intervals varying from one to seventeen weeks. The healthy formation of blood is known to be disturbed for a time after the extirpation of the organ in question; the white corpuscles are increased in number, while the red disks are diminished. Zesas found that the lymphatic and thyroid glands, with, perhaps, the liver, take on the functions of the spleen. He also came to the conclusion that the removal of the thyroid gland, as well as the spleen, prevented the proper re-establishment of normal hæmopoiesis. The spleen is therefore believed by Zesas to be concerned in the conversion of the white blood-corpuscles into red ones.—*Lancet*, June 23, 1883.

The Parasites of Marsh Fevers.—Dr. Laveran, of the Val-de-Grâce, in a communication to the Paris Hospital Society (*Union Méd.*, June 12 and 14), states that the observations which he formerly made in Algeria as to the presence of well-defined parasitic organisms (which he describes at length) in the blood in marsh fevers have been fully confirmed by subsequent researches. Their pathogenetic character has been proved by a large number of facts which enable him to come to these conclusions: 1. These parasitic elements exist always in the blood in cases of impaludism; and even when the examination of the blood of the living does not always exhibit them, they are still always to be found at least after death in the capillaries of the spleen. 2. They are always found in direct ratio with the severity of the case. In individuals who succumb through some complication in simple intermittent they are found only in small numbers in the liver and spleen; but in those who die from pernicious fever they exist in large numbers in all the organs and vascular tissues. 3. They precede a paroxysm of the disease, and when they are found in the blood we may almost certainly predict that a paroxysm is about to occur, although no elevation of temperature or other morbid sign exists. 4. These elements are never found in diseases unconnected with impaludism. 5. These elements disappear rapidly under treatment by quinine.—*Med. Times and Gazette*, June 23, 1883.

CONGENITAL DIVERTICULUM OF THE LEFT VENTRICLE.—A rare and curious example of cardiac abnormality has been recorded by Dr. Gibert, of Havre (*Progrès Méd.*, June 9th), as occurring in an infant who lived to the age of ten months. The child was born with a ventral hernia, the abdominal wall being defective in the middle line from the umbilicus upwards. A large pulsating vessel was noticed to be present together with the hernia, and as time went on, this vessel increased in size, till, at the time of death, it was as large as the finger. On examination, it was found that the diaphragm was also defective, so that the pericardium opened into the peritoneal cavity, and projecting into the abdomen was a pouch-like diverticulum, connected with the apex of the left ventricle, with muscular walls, and internally marked by fleshy columns like the ventricular cavity itself. This diverticulum was thirty-eight millimetres in length, and shaped like the finger of a glove. Dr. Gibert suggested that the non-closure of the ventral wall was probably due to the presence of this cardiac deformity; but the converse hypothesis, that the pouching of the ventricle depended on the defect of the diaphragm and abdominal wall, seems to be held by Dr. R. Blanchard, who made a further dissection of the specimen, for he speaks of it as being the congenital formation of a kind of true infundibular form of aneurism of the apex of the left ventricle—"a fact the more curious, because at that period of life the left ventricle only plays a very subordinate part, and this protrusion of a portion of its wall cannot, therefore, be attributed to an excess of internal pressure." However, we are not aware that in any recorded case of pericardial deficiency a similar ventricular aneurism has been observed. Dr. Peacock, who refers to several cases of defect of the pericardium, including the classical one referred to by Baillie, makes no mention of such an abnormality in his work on *Malformations of the Heart.* In cases of ectopia cordis, the organ is generally misplaced in whole or in part; one case mentioned by Dr. Peacock as having been published by Dr. O'Bryan most resembles Dr. Gibert's, for in it a portion of the left ventricle protruded through a triangular aperture at the anterior and upper part of the abdomen, produced by the absence of the xiphoid cartilage, and the fibres of the diaphragm inserted into it.—*Lancet*, June 23, 1883.

THE INFLUENCE OF THE ELECTRIC LIGHT ON THE HUMAN EYE.—In discussing the value of any particular source of artificial light, says PROF. MAUTHNER (*Wien. Allgem. Med. Zeit.*, No. 10, 1883), three qualities must be especially regarded: 1. The steadiness of the light; 2, the strength of the light; 3, its composition. From its complete failure in point of steadiness, the arc-light must be at once rejected from the category of lights suitable for the human eye. The incandescent light, on the other hand, deserves a prominent—if not a leading—position. As regards its strength or intensity, also, it fulfils all requirements, since it can be modified or intensified at will. The composition of the lights habitually used hitherto has shown a preponderance of yellow rays. In the electric light, however, the short-wave rays predominate—*i. e.*, the violet rays. To the human retina, blue or violet tints are more agreeable than yellow, and hence from its composition, as well as from its steadiness and adaptability, the light of the incandescent lamp is especially adapted for the use of the human eye. Distinctness of vision and the perception of color are both increased under the electric light—facts which might be theoretically held to involve an overstrained retina. Such a theory is not, however, borne out by practical experience; it is only where the light employed is unsteady that any ill-effects have been observed. It may be considered as an established axiom that the brilliancy and composition of any light are as nothing in respect of its value as an illuminating medium for ordinary uses, compared with its constancy and steadiness. In the incandescent lamp, no combustion takes place, and hence no consumption or vitiation of atmospheric air is induced. From a theoretic point of view, therefore, no objection can be raised against the use of the incandescent electric lamp: its full value as an illuminator is probably not yet ascertained.—*London Med. Record*, June 15, 1883.

WOUNDS OF THE VAGUS NERVE.—The following case is of interest in relation to the question of the possible effects which may follow division of the par vagum on one side of the neck. The patient was a man aged forty-nine years, the subject of a tumor in the neck of long duration, which, in the course of eight weeks, rapidly increased in size, induced much pain, and was associated with marked emaciation (*Berliner klin. Wochen.*, No. 21). The tumor occupied the left side of the neck, displacing the larynx to the right; it was of the size of two fists, but little movable, and was crossed by large veins. No signs of pressure on the vessels or nerves were detected. The lungs yielded no physical signs of disease. Notwithstanding the connections of the tumor, its removal was decided upon. Much difficulty was encountered in the course of the operation. The internal jugular, being adherent to the tumor, was ligatured and divided. The vagus nerve was apparently much displaced, for it was divided under the notion that it was the descendens noni. Later on in the operation the vagus was again cut through, so that a portion of it, about six inches long, was removed. After the operation, the pulse was 120. Some râles could be heard in the left lung, and the left vocal cord was paralyzed. Six hours later the pulse was 90; the respirations were 30. After this the patient did fairly well till the tenth day, when fever set in; and on the twelfth a rigor occurred, which was repeated the next day. The patient died on the fourteenth day, only a little purulent sputa having been coughed up. At the autopsy, some broken-down blood-clot was found at the site of each ligature on the internal jugular vein, but not an extensive thrombosis. The muscles of the left vocal cord were already in a state of fatty degeneration. In the bronchial tubes of the left lung only purulent matter was seen; the right lung was œdematous and congested, but there was no bronchitis. The brain and the heart showed no morbid signs. Dr. Riedel, who had performed the operation, regarded the unilateral bronchitis and disease of the left vocal cord as directly dependent on the removal of the large piece of the left vagus nerve in the neck. The pyrexia and the rigor which ushered in death were looked upon as probably of embolic origin, though there was no post-mortem evidence to substantiate this view—*Medical Times and Gazette*, June 23, 1883.

Prevention of Infantile Diarrhœa.—The *Bureau d'Hygiene* of the City of Rheims, France, in July of last year, made a slight change in the form of death-report required in cases of infantile diarrhœa, which has been productive of very instructive results. Children dying from this disease were divided into two classes—those nourished by mother's milk, and those brought up by hand. From July 1st to December 31st, thirty-one infants nourished at the breast and two hundred and seventy-two brought up *au biberon* died of infantile diarrhœa. "This teaches us nothing new," says M. Langlet, in his annual report; "but it is one of those truths which cannot be too often recalled."

To place the true value on M. Langlet's facts, we should know the relative proportions of the two classes of infants. However, it can hardly be supposed that the bottle-fed children are to the nurslings as nine to one.

Alum in the Treatment of Phthisis. — Many physicians, both on the Continent and in some of our colonies, as well as at home, accept the doctrines of Koch without question. One of the natural consequences of this acceptation is the search after some remedial agent which shall possess the capacity of checking the growth of the micro-parasite which is the reputed chief etiological factor of the disease. Dr. Julius Pick has put on record the results of his experience in this matter with the preparations of alum (*Wiener med. Wochen.*, No. 19). The author seems to consider that he has proved that the benefits which accrued from the employment of these therapeutical agents were marked, and all that could be desired. The outlines of one case, which was diagnosed to be tuberculous infiltration of both lungs, chiefly at the apices, are faithfully recorded. At the beginning of January of this year the treatment was commenced, and consisted of an inunction with fat, performed twice daily over the whole body, of a diet composed of bread and milk, together with the internal administration of a pill three times a day two hours after food. This pill consisted of a quarter of a grain of metallic aluminium, a grain and a quarter of undried alum, with the same quantity of pure carbonate of lime. After eight days the diarrhœa ceased, the appetite improved, the fever abated, and the night-sweats became less. Notwithstanding this favorable progress, the composition of the pill was somewhat altered; instead of the undried alum, the same dose of an extract of the malate of iron was substituted, and some extract of taraxacum was used to make up the preparation. Two of these pills were prescribed in the morning, three at midday, and two at night. The inunction with fat was proceeded with. It need hardly be said (for the case would scarcely have been published else) that the physical signs and symptoms of the disease gradually diminished to a practical zero. The correctness of the original diagnosis is of course taken for granted. The above sketch is a fair representation of the illogical mode of thought current among not a few medical men.—*Med. Times and Gaz.*, June 23, 1883.

Resection of the Pylorus.—Dr. Van Kleef performed this operation, in January last, upon a woman who had stenosis, due to ulcer. The recovery took place without accident, and by the latter part of May the patient's weight had increased thirty pounds.—*Gaz. Degli Ospitali*, May 27, 1883.

Paralysis of the Oculo-motor Nerve during Menstruation.—At a meeting of the Society of German Physicians in Prague on March 2 (*Wiener Med. Blätter*, March 15), Prof. Hasner showed a case of periodical paralysis of the left oculo-motor nerve, occurring along with menstruation. The patient, a girl, aged 17, was perfectly well until the first beginning of menstruation, when paralysis of the left eyelid appeared on the first day, and lasted, gradually improving, until the third day, when it disappeared with the cessation of the menses. This recurred at every menstrual period. The case seems to be unique, and Prof. Hasner considers it to depend on hyperæmic pressure in the region of the root of the left oculomotor nerve.—*London Med. Record*, June 15, 1883.

Post-hemiplegic Disorders of Movement.—A valuable communication on the above subject by M. Demange will be found in the May number of the *Revue de Médecine;* it is based on a study of eleven cases, of which nine proved fatal. In each of these an autopsy was made, and a drawing is given of the morbid appearances found in the brain. The cases are all very well reported except in one particular, and that is, that from first to last there is no mention of the ophthalmoscopic appearances in any of the patients. In this respect, however, M. Demange does not differ from his compatriots, for we may say, without fear of contradiction, that it is quite exceptional to find any note as to the state of the optic disk in the cases published in the various French journals. Notwithstanding this omission, however, the paper constitutes a distinct advance in our knowledge of the different varieties of post-hemiplegic movement. These movements, according to the author, may be divided into two groups—in one they supervene spontaneously, apart from voluntary movements (of this kind are hemi-chorea, hemi-athetosis, and hemi-paralysis agitans); in the other groups the movements are produced only during the performance of voluntary acts (of this kind are hemi-ataxy and hemi-tremor of the type of disseminated sclerosis). These movements may coincide in the same patient, or they may succeed one another. In all the patients, of course, there was hemiplegia, and in all there was hemi-anæsthesia. As regards the lesions found, in one it was almost confined to the posterior segment of the internal capsule (case of hemi-chorea); in six cases the lenticular nuclei were affected (in some of these the internal capsules were also involved, in others the optic thalami—one case of hemi-paralysis agitans, four cases of hemi-athetosis, and one of hemi-sclerosis disseminata); twice the lesion was cortical and subcortical, at the region of the motor convolutions, the central ganglia being quite normal (one case of hemi-athetosis and one of hemi-ataxia). No special seat, then, can be assigned to the lesion, judging from the form of the trembling. The anatomical condition which gives rise to the production of the trembling would appear to be the irritation of the motor fibres at any point of their course, whether in the internal capsule, the lenticular nucleus, optic thalamus, or motor convolutions, and the form of the trembling would, in the author's opinion, be dependent, not upon the seat of the cerebral lesion, but upon the state of the muscles of the paralyzed side—muscles whose tone and contractility vary according to the patient, the duration of the hemiplegia, and the state of descending degeneration of the pyramidal fibres. The author sums up the conditions necessary for the production of these movements as follows: 1. The hemiplegia must not be flaccid and complete. 2. The secondary contraction must not have given rise to an absolute rigidity. The paper concludes with some remarks on bilateral hemiplegia due to symmetrical cerebral lesions.—*Med. Times and Gaz.*, June 23, 1883.

JABORANDI IN HEART DISEASE.—PROF. RIENZI has used powdered jaborandi, grs. xlv–ʒiss during the day, in two cases of aortic insufficiency with endarteritis. serous expectoration, dyspnœa, painful palpitations, frequent and quick pulse, and murmurs at the base of the lung. After a few days' treatment, the sounds were lessened, the pulse was less frequent, and the painful palpitations had ceased. At the same time there was quite profuse sialorrhœa, and increased intestinal secretions. He believes that jaborandi has a double action, in regulating and sustaining the energy of the cardiac contractions, and in increasing the excretions from the economy. From this double action he deduces its utility in cases of failure of energy in the contractions, and in cases in which there are œdema and congestions. —*Cronica Medico-Chirurgica*, May, 1882.

TREATMENT OF PHTHISIS WITH IODOFORM.—Since Semmola's communication on the use of iodoform in phthisis to the International Medical Congress in Amsterdam, his experiments have been repeated, and with satisfactory result. Ciaramelli, De Renzi, Fasano, and other Italians have confirmed his statements (*Lo Spallanzani*, January and February, 1883). Iodoform acts in phthisis and chronic bronchial catarrh as an anæsthetic, antiseptic, and alterative. The best results are obtained in incipient phthisis, which is often cured. In advanced cases this remedy is very useful, lessening expectoration, moderating the accesses of cough and fever, and arresting the progress of caseation—in a word, prolonging the patient's life. Iodoform has been used by inhalation, either by rubbing the patient's chest with an iodoform ointment, or by making him inhale essence of turpentine containing iodoform in solution. This method, though most rational, is so largely objected to by patients and their friends because of the disagreeable smell of the iodoform, that it cannot be extensively used. Or it may be given in a pill with extract of gentian or other extract, beginning with one grain a day, increasing the dose as toleration is acquired to six or eight grains a day.—*London Med. Record*, June 15, 1883.

ICHTHYOL.—UNNA (*Deutsche med. Zeitung*, Nov. 17, 1883, and *Monatsschr. für Prakt. Dermat.*, Nos. 11 and 12, 1882) has used with great success a new bituminous substance containing a large amount of sulphur, and to which the name of ichthyol is given. It is partially soluble in alcohol and ether, and perfectly soluble in these combined. He recommends its use (10 per cent. with vaseline) to paint on the joints in acute rheumatism, which should then be wrapped in wadding; he says it gives immediate relief from pain. He uses stronger ointments (20 to 30 per cent. in vaseline) in chronic rheumatism, lumbago, and neuralgia. He recommends it to be inhaled with steam, a tablespoonful to one or two litres of water; or to be sprayed on the throat, 5 per cent. dissolved in equal parts of ether and alcohol. He uses 1 per cent. watery emulsion in the early stages of gonorrhœa as an urethral injection, and he thinks very highly of it in eczema in 50 per cent. ointment with vaseline for adults, and 20 per cent. for children. In nascent eczema he begins with 20 per cent., and later on uses 10 per cent. He has found great advantage in obstinate eczema from an ointment made by boiling 10 parts of litharge with 30 parts of vinegar until 20 parts remain, and then adding 10 parts each of olive-oil, lard, and ichthyol.—*London Medical Record*, June 15, 1883.

EPIDEMIC PNEUMONIA.—An interesting epidemic of croupous pneumonia, which seems to point to its infectious character, is the subject of a paper by DR. HEINRICH SCHMIDT, of Königsbrunn, in the *Berliner klin. Wochenschrift*, No. 23. The outbreak occurred at Zang, a village of 549 inhabitants, situated on the Aalbuch, and surrounded by woods. The inhabitants are hard-working, and their food is coarse and frequently scanty. The water-supply is bad. Typhoid fever occurs only sporadically, and ague is unknown. An epidemic of measles occurred amongst the children in the month of March, 1882. Ordinary croupous pneumonia occurs pretty frequently. A case of pneumonia occurred on April 5, which, however, does not belong to the epidemic under notice. The first case of the epidemic occurred on May 11, and between that date and June 18 seventeen cases occurred. On July 10, a case of pneumonia also occurred, but this was not part of the epidemic. Two of the cases ended fatally, and four ran an abortive course. The cases all occurred in neighboring houses. Six cases occurred in a very poor family, whose hygienic surroundings were very bad. The period of incubation seems to have been in most cases about five to eight days. The weather in May was cold, but warm in June. Most of the epidemics of pneumonia have been described as occurring in closed places, usually institutions or prisons. Kerchensteiner observed an outbreak of pneumonia which spread like an epidemic, and was of a typhoidal character. The overcrowding of the sleeping apartments he considered as a most favoring circumstance. Inoculation of animals with the blood of these pneumonic patients gave no result. Penkert, in the *Berliner Wochenschrift*, Nos. 40 and 41, 1881, described an epidemic occurring in a small place of about 700 inhabitants. He considered that the infectious material had been carried from a neighboring churchyard by the wind to a school where the first twelve cases occurred, and that the disease afterwards spread from person to person. The epidemic was of a mild character, differing from most epidemics described. The *Deutsche Vierteljahrsschrift für öffentliche Gesundheitspflege*, 1882, Bd. ii., pages 366 and 367, mentions an epidemic comprising seven cases occurring in Uster, three of which ended fatally. The cases were described as typhoidal pneumonia. In Börner's *Jahrbuch der practische Medicin*, 1882, p. 239, an epidemic is mentioned by Schwede and Münnick. It comprised fifteen children out of fifty, and occurred within thirteen days in a small village, whilst in the neighborhood no case occurred. Epidemics of pneumonia have been noticed in garrisons—in the First Army Corps, at Königsberg, Dantzic, and Grandenz, commencing in January, 1875, and ending in July, 1875. Another epidemic occurred in the Fourth Army Corps in the winter of 1875 and 1876. The symptoms in both epidemics were almost the same—prodromata, with various general symptoms, high fever, and at the commencement no distinct local signs in the lungs; next, severe head-symptoms, and profound prostration of strength; then local mischief in the lungs, and with it increased rise of temperature; no true crisis, or only after the seventh day, then diarrhœa. Very frequently there was considerable swelling of the spleen and liver, with slight jaundice, marked and rapidly occurring heart-failure.—*Medical Times and Gazette*, June 23, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, JULY 14, 1883.

THE GRIEVANCES OF THE PLUMBER.

THE master-plumbers of the United States have held a National Convention in New York, in which they have duly considered their troubles, and the causes and remedies for the same.

Their grievances, as set forth in the address of Mr. Remick, of Philadelphia, which seems to have been accepted as an exposition of the views of the convention, are as follows: "It is a general feeling among plumbers all over the country that the tone of our trade is lowered; we are made the butts of the penny-a-liners of the press, which, naturally, has an effect on the minds of the public; our legitimate trade is filched away from us by unscrupulous dealers; we are held up to the public gaze as ignorant and reckless individuals who tamper with the lives and the health of our customers. A newly-invented profession is sprung upon the world, called sanitary engineering, which proposes to its confiding patrons to guard and protect them against their insidious enemy, the plumber. Boards of health, too, lend their aid to these magniloquent braggarts by publicly setting the seal of their disapproval on practical skill and experience, and their unqualified indorsement of book-taught experts and newspaper scientists. It is a fact to-day that the men whose lives are spent in the solution of, and whose pursuits lie close to, the sanitary problems of the day more than any other, are ostentatiously ignored, and the claims of raw graduates from medical or other schools are as brazenly thrust in the face of the public."

The remedy proposed for these evils appears to be to get all the plumbers in the country to join an association, formed on the strictest trade-union principles, the members of which are not to purchase materials from any dealer who sells to any other parties than plumbers, and who, probably, are to refuse to work in accordance with plans made by any sanitary engineer or with suggestions of any one who is not a master-plumber.

The absurdity of the complaint is only equalled by the folly of the remedy proposed.

What are the facts in the case? A very large proportion of the men who advertise themselves as plumbers are incompetent mechanics who have never served any sufficient apprenticeship, and are unfit to be trusted with anything but the simplest kind of work. A very considerable number of the plumbers who are good mechanics have forfeited the confidence of the public, because they have taken contracts at prices for which good work and materials could not be furnished, and have furnished poor materials and done bad work in order to make it pay, thus playing into the hands of the so-called "Jerry builders."

That the tone of the plumbing trade has been lowered there is no doubt, but the plumbers themselves are responsible for it. The remedy is not a trade-union, in which the skilled and honest workman is to stand on the same level as the incompetent and ignorant man who knows little more than how to wipe a joint. The true remedy is a system of registration of competent plumbers, the competency to be determined by adequate tests, and it is to secure this that association on the part of the really skilled men can produce the most valuable results.

As to the claim that plumbers alone shall furnish materials, and that every one is to accept the plumber's dictum as to what fixtures shall be used, and how the pipes shall be arranged, it is so absurd that the mere statement is a sufficient refutation. Equally absurd is the hostility evinced towards sanitary engineers and health boards and officials. These are in fact the best friends and most powerful auxiliaries of the competent and honest mechanic. They are teaching the public the importance and value of good work, and every job of skin-plumbing which they condemn, and every piece of blundering stupidity which they expose, directly tends to raise the tone of the trade. The sanitary engineer or inspector does not compete with the plumber—he makes work for him;—if he competes with any one, it is the architect or builder. How far it is necessary or desirable that the Sanitary Inspector should have a practical knowledge of plumbing is a question—undoubtedly such knowledge would be useful, yet the best sanitary inspectors in this country or in Europe probably could not set a closet or bath-tub and do all the work with their own hands.

The improvements which have been made of late years in systems of house-drainage, to secure proper traps and adequate ventilation, have not received the recognition of their merits which the educated part of the public now gives them through the exertions of plumbers, even if the latter have devised them, which is not the case for all of them by any means.

If a much larger proportion of physicians than is now the case, interested themselves in the subject of house-drainage, it would be the better for the plumbers as well as for their patients, and we believe that most competent mechanics would promptly admit this.

We are glad to learn, however, that some plumbers at all events are sensitive to criticism, for it is an encouragement to continue it, and if they do not wish to be ridiculed they certainly should not accept as grievances the statements set forth by Mr. Remick.

DESQUAMATIVE PNEUMONIA—BUHL'S PNEUMONIA. DOES IT EXIST?

It is well known that more than twenty-five years ago, Buhl suggested this term for an acute pneumonic process, which consists primarily in a swelling, nuclear proliferation, and desquamation of the epithelial lining of the air-vessels—phenomena which really depend upon a serous infiltration of the alveolar walls, the parenchyma of the organ. It occurs in three degrees: the first and least marked being one of the symptoms of severe general processes, bearing the same relation to them as do alterations in the kidneys, heart, muscles, etc., which are usually termed "parenchymatous." Whence the term parenchymatous pneumonia would also be appropriate for it.

The second form, which is inflammatory from the beginning, Buhl terms *genuine desquamative pneumonia*. It bears the same relation to the first form that true parenchymatous nephritis does to collateral affections of the kidney in severe constitutional disease. In this form, to the phenomena of desquamation are added a hyperplasia of the connective-tissue cells of the alveolar walls and a decided pigmentation of the latter. The process is more really a "parenchymatous" inflammation, and, while recovery is not impossible, it generally passes over into cirrhosis or fatty degeneration.

The highest degree is that which terminates in fatty degeneration, and is known as cheesy tuberculous pneumonia. The process usually extends through an entire lobe, and especially an upper lobe, or even an entire lung, in which event it begins in an upper lobe, and extends thence downward. The cheesy tubercular pneumonia, always primary, is the localized expression of a constitutional tendency, without a focus of infection. As such, it is opposed to miliary tuberculosis, which is always secondary, and due to an infectious irritant.

Well described and defined as appeared to be this process, it is evident that, if the most recent doctrines growing out of the discovery of the bacillus tuberculosis prevail, the fundamental idea on which this third form of desquamative pneumonia of Buhl is based is withdrawn. If it is the specific bacillus which causes tuberculosis, then there can be no tuberculous pneumonia, the result of a constitutional tendency, and although it is not impossible that a rapid caseating pneumonia may supervene upon a disseminated miliary tuberculosis, such supervention must be very rare. And in a recent paper (*Deut. med. Wochenschr.*, May 2), Nauwerck attempts to prove by observations at the post-mortem table, and by the microscope, that this *a priori* deduction is correct. His position at the Zürich clinic gave him the opportunity of seeing many cases corresponding in all respects in their clinical histories with those described by Buhl as characteristic of his desquamative pneumonia (lobar tuberculous pneumonia)—that is, the patients had scarcely reached or slightly passed their twentieth year; frequently belonged to tubercular families; had previously shown pulmonary symptoms; the attack commenced like croupous pneumonia, but in an upper lobe of the lung, extending thence to a part or whole of a lower lobe, sometimes partially improving, never terminating in recovery, but after weeks or months of illness in death. Nauwerck's most rapid case died in six weeks. At the autopsies, the affected lobes in the rapid cases were in a state of more or less diffuse caseous infiltration; in the older ones were noted cavities, an overgrowth of cicatricial connective tissue, etc., and most frequently the lobes were in a state of slate-colored induration, uniformly perforated by cavities, producing an appearance which he compared to that of a coarse sponge.

Here, however, the correspondence with Buhl's picture ceased. Microscopic and even closer macroscopic examination in no way sustained the diagnosis of primary cheesy pneumonia. In no instances were there old alterations at the apex, pleural adhesion, or slate-colored induration; while there were always present cavities communicating with the branches of the bronchial tube, and Koch's tubercle-bacilli were found in all sections, whether through cheesy portions, or through parts in which the normal structure was not destroyed by the cheesy infiltrate.

From such facts as these, Nauwerck concludes that all cases corresponding clinically with Buhl's description, and anatomically presenting the above described features, including cavities at the apex, originate not as lobar, but as confluent lobular pneumonias; that they are caused by the aspiration of cheesy purulent matter, loaded with specific bacilli, in which the preëxisting cavity in the apex always abounds. These are drawn from the cavity into the communicating bronchus, and thence into the smaller bronchioles leading to the infundibula, in which they light up tubercular processes.

INFANT MORTALITY.

As the season has arrived when a greatly increased death-rate amongst infants is to be expected, no effort should be spared in the prompt use of measures known to be effective in counteracting or lessening the preventable causes of sickness amongst the young. The appalling waste of human life in the summer months from causes plainly within control, suggests a broad and fruitful field for the noble work of the sanitarian and philanthropist. A marked increase in mortality from influences associated with the season, is inevitable, notwithstanding the best hygienic surroundings; but a large proportion of the excess of deaths, especially among those of tender years, can be clearly traced to a violation of the precepts of sanitary law.

Ignorance, poverty, and crime, are the conditions mostly at fault in the class of society from which the excessive mortality is derived, and it is to the improvement and amelioration of these conditions that special and persistent effort must be directed, if tangible results are to be expected.

Upon the municipality there rests a heavy responsibility. The removal of all injurious influences strictly within public control is a bounden duty. Thorough cleanliness of the streets and surroundings of habitations, particularly in densely populated districts, prompt removal of all refuse matter, an adequate supply of pure water, the rigid inspection of food supplies, and the judicious inspection of habitations with the object of improving the homes of the poor: are all matters that require the most constant attention at this season of the year.

The instruction of the ignorant with regard to the management of infants during the heated term is a subject which has of late attracted especial attention. Tracts containing plain instructions to mothers have been and should be each year freely circulated in most of the large cities, and the importance of this practice cannot be too highly estimated in view of the extreme ignorance on the subject existing among the masses.

Public effort though indispensable is necessarily restricted, and must be largely supplemented by the labors of the benevolent and philanthropic. Noble efforts are being made by individuals and charitable organizations to improve the conditions of the poor by instruction, advice, and substantial assistance in cases of absolute need, and in warding off sickness, and in relieving the sick and suffering amongst the destitute. The procurement of temporary homes in the country for the children of the poor, under the direction of the Children's Country Week Association, has been the means of saving many a life which would otherwise have been sacrificed in the season of torrid heat.

The Sanitarium Association, which daily provides, free of cost, the advantages of fresh, pure air and wholesome food, upon an island in the Delaware, for thousands of children gathered from the foul courts and alleys of the city, is another means of overcoming the deadly influences which are always operating on infant life in crowded districts in the summer season. Akin to these institutions are the Sanitarium at Baltimore, *The Tribune* fresh-air fund, and the St. John's Guild in New York City, their object being to afford poor children an opportunity for obtaining fresh and pure air during the warm months. The Children's Seashore House, at Atlantic City, for Invalid Children, should also be mentioned as one of the successful means of combating the injurious influences of summer life in the city, though the scope of its usefulness is necessarily limited.

Such institutions may be taken as illustrations of the agencies which are most serviceable in contributing to the comfort and enjoyment of the children of the poor, and in warding off sickness, restoring health, and preventing the needless sacrifice of human life. As such, they commend themselves to the hearty sympathy and liberal support of the charitable.

CAUSES OF ALBUMINURIA.

Pentzold has recently reported to the Congress of German Physicians the results of a most important series of experiments upon animals, made with a view to determine the effect of different substances used as foods and medicines in producing albuminuria.

The first agent experimented with was alcohol, on account of the importance which has always been attached to it in relation to renal diseases. Twenty-five to thirty cc. (about f℥j) were administered (daily?) to a dog, and in the course of three months, albuminuria and decided fatty degeneration of the renal epithelium supervened. The ingestion of amylic alcohol also, the usual alcoholic impurity in whiskey, was followed by death from acute nephritis in seven weeks; as was also the ingestion of 200 cc. at one dose.

In like manner the presence of ergot in moderate quantity in the bread consumed by dogs produced albuminuria and fatty degeneration. So also mustard ingested for six months produced temporary albuminuria and fatty degeneration of the uriniferous tubules. Pepper acted similarly, and radishes were followed each time by an albuminuria lasting a few days. Even tea produced in one case decided albuminuria, and in certain small dogs the administration of twenty grammes a day was followed by a sediment composed of white blood-corpuscles, fatty epithelium, and granular tube-casts.

In consequence of the frequency of albuminuria in cases of diabetes, Pentzold fed dogs with ordinary grape-sugar and very soon produced albuminuria, the dogs dying in one month after having taken 1400 grammes; and after death there was found decided fatty degeneration of the cells lining the convoluted and straight tubes, while there was no sugar in the urine.

While it was impossible to estimate from these experiments the effects of the same substances on human beings, Pentzold very properly characterizes them as pointers whence we may regulate the use of certain food elements by albuminuric patients.

As to drugs, there is an unfortunate discrepancy in the report (*Deut. med. Woch.*, May 16), and we look anxiously for a revised and corrected statement. Thus Pentzold found that tannin, whether in large or small doses, was without effect; sodium acetate diminished the secretion of albumen considerably; potassium acetate, pilocarpine, and digitalis, on the other hand, in large doses, increased it—pilocarpine fourfold, and digitalis twofold. In the next paragraph, however, Pentzold in speaking of the therapeutic deductions which may be made from the latter series of experiments, says tannin, digitalis, and pilocarpine produced no alteration in the secretion of albumen; on the other hand, sodium and potassium acetate in moderate doses appeared to exert a favorable influence. Notwithstanding these descrepancies we think it important to lay these facts before our readers without delay.

Pentzold advised, in conclusion, that experiments should be made with digitalis, conducted in such a way that the blood-pressure be kept under accurate observation, with a view to determine whether increasing or lowering the blood-pressure influenced in any way, the filtration of albumen through the kidneys.

SOCIETY PROCEEDINGS.

A GOOD deal of our space has, of late, been naturally devoted to the annual sessions of State and other medical societies. Their proceedings may be fairly considered as the mirrors, reflecting the operation and position of the profession to date, and as such they are worthy of attentive perusal.

Any one who has even cursorily examined these proceedings as they have appeared in our pages during the past three months cannot fail to have noted that there are great differences in the quality as well as the quantity of the material which makes them up. At the same time we think it well that good, bad, and indifferent should all be published. The opportunity of comparison is afforded, and the societies which are deficient, noting their deficiences, can labor to correct them, and those whose work is creditable, be stimulated to make it more so.

It must be admitted, however, that the proceedings of our societies, even at their best, compare but ill with those of foreign countries, — at least with those of Germany, of England, and of France. Any one who may have read the proceedings of the Society of German Physicians at its recent session at Wiesbaden, or of the 12th Congress of German surgeons at Berlin, or of the Academy of Medicine of Paris, cannot fail to have been struck with the originality and practical value of the papers read before them, and the large amount of information brought out by the discussions. This is because these discussions are participated in by the leaders in the profession, while with us the best men, as a rule, keep aloof from the meetings. We have already presented to our readers the essential portions of some of these.

The first question which naturally suggests itself is, Why this superiority? Doubtless more than one element contributes to it. In the first place, the more thorough training and broader general and professional culture of the foreign physician qualify a larger number to become contributors, through experiment and observation, to our knowledge. Again, of those at home qualified to observe and pursue original investigations, many are so tramelled by the multiplicity of duties which naturally devolve upon them in the methods of practising and teaching still necessary in this country, that comparatively few are left who have the time to investigate. Finally, we regret to have to say that the organization of our Societies is generally such as to discourage the interest and attendance of those who might, by reading papers and joining in discussions, furnish much valuable information. Too often office is given to those who are least qualified, and who would never be thought of for these positions if they themselves had not sought them, or if some absurd notion of the geographical distribution of office had not influenced their appointment.

We feel, however, that a better day is dawning upon us, and its results are seen in the proceedings of the Societies organized for the development of the specialties, where no such elements as those last referred to are apparently allowed to operate, and where good work is being done; as witness the Proceedings of the Laryngological and Neurological

Societies, which have recently concluded their sessions in New York.

So, too, as the general and technical culture of our medical men becomes broader, and their leisure for special work greater, we may expect to see these influences operate in securing us a better class of communications, and more original investigation.

REVIEWS.

Students' Guide to Diseases of the Eye. By Edward Nettleship, F.R.C.S., Ophthalmic Surgeon to St. Thomas' Hospital and to the Hospital for Sick Children. Second American, from the second revised and enlarged English edition. With a Chapter on Examination of Color-Perception, by William Thomson, M.D., Professor of Ophthalmology in Jefferson Medical College.

The early demand for a second edition of this excellent little manual shows that it has met with the appreciation and success that it deserves. It has been somewhat enlarged, a number of new woodcuts have been added, and some changes have been made by the author in his arrangement of the contents. The chapter by Dr. Thomson on the examination of railway employés gives interesting and instructive information upon a subject that has recently attracted much attention, not only in the medical profession, but in the general public as well.

The student or physician who seeks to obtain a practical knowledge of the affections of the eye without too much sacrifice of time, imperatively demanded in many directions, will nowhere find a more satisfactory *multum in parvo* than is offered here.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, April 4, 1883.

The President, S. D. Gross, M.D., LL.D., D.C.L., in the Chair.

Dr. J. M. Barton read a paper entitled

SEPARATION OF THE EPIPHYSIS OF THE HEAD OF THE FEMUR.

This accident is so rare that it is scarcely mentioned in any of the great systems of surgery.

Hamilton, in his edition of 1875 of his work on *Fractures and Dislocations*, reports four cases, and states that "these four constitute the only examples of this accident which I find reported, or of which I have any knowledge, and although there may be much reason to suppose that the diagnosis was correct in each instance, I cannot regard any one of them as actually proven." In his last edition he has added two very briefly reported cases to his list. Under these circumstances I regard the history of this case, and the manner in which the injuries were received, as worthy of being placed upon record.

In May, 1881, I saw, with Dr. Minich, of this city, John L., aged 15 years, who a few days before, while working in his father's mill, had received some injury to his hip. While crossing the yard, carrying a large bundle, a companion, in play, pushed against him, the bundle came to the ground, and he saved himself from falling by resting his hands on it. While in this position, leaning forward with his hands resting on the bundle, a second push turned him over, and he came to the ground seated, supporting his weight by his hands. His hip came but lightly in contact with the ground, if at all.

On examination we found one inch of shortening; the foot was everted, though somewhat stiffly, the outer edge of the foot not lying on the bed, as in senile intracapsular fracture, but making an angle of about twenty degrees (20°) with the surface of the bed. The knee and small of the back were in contact with the bed at the same time. The fascia lata was relaxed. The trochanter was higher, more prominent, and nearer the anterior superior spinous process than its fellow of the opposite side. There was no spasm of the muscles about the hip. The buttock was flattened, and the gluteo-femoral crease was not well marked.

Under ether the limb was as readily and fully rotated as its fellow, the trochanter describing a large arc of a small circle, or, in other words, rotating on its own centre, and not increasing its distance from the median line of the body. On extending the limb it readily acquired its full length, and all deformity disappeared, both shortening and prominence of trochanter immediately reappearing on relaxing the extension.

During these manipulations crepitation of an unusual kind was felt, as though large surfaces of denuded bone were being rubbed on each other. Placing the patient on his side, the knee of the injured leg can be made to go three inches further posteriorly than its fellow. The wasting of the buttock suggested further inquiry, and it was found that the boy had slightly limped for some weeks, and had had pain in the inner side of the knee. Yet notwithstanding these evidences of beginning coxalgia, he had been able to work and take an active part in play with his companions. Within a week prior to the accident he had engaged actively in a game of foot-ball, using the now injured limb to kick the ball, and felt no inconvenience from so doing.

The case was readily determined to be none of the usual dislocations, but the presence of the inflammatory action suggested the possibility of, 1st, a rupture of the "Y" ligament, and a dislocation without characteristic deformity. 2d. An unusual dislocation. 3d. The absorption of the head of femur and of acetabulum and resulting dislocation on slight violence. 4th. fracture of the neck or rather separation of the epiphysis in a congested and perhaps inflamed bone.

The usual and unusual dislocations were readily excluded. 1st. By the absence of the characteristic deformity and the inability to find the head of the femur in any unusual situation. 2d. By the ease which under ether, full extension was made, obliterating all deformity, and the immediate reproduction of all symptoms on relaxing the extension. 3d. That during full rotation of the limb, carrying the toes from full inversion to full eversion the trochanter rotated on its centre and its distance from the median line of the body was not increased. The dislocation occurring in advanced coxalgia was excluded. 1st. By the patient's ability to freely and violently use the limb immediately prior to his injury. 2d. The fact that the deformity was immediately reproduced on relaxing the extension; in cases of dislocation in advanced hip-disease, the head of the femur catches in and perhaps remains for a short time in the enlarged acetabulum during examination. 3d. The same test as was used to exclude the other dislocations, viz., the distance of the trochanter from the median line not being increased on full rotation.

The diagnosis of separation of the head of the femur was made, the patient was placed in bed with extension, sand-bags, and additional support at the region of the injury. He was kept in this position in bed five weeks, during which time there was less than half an inch of shortening. On carefully removing the extension at the expiration of this period, the original deformity immediately returned.

The boy wore, for a few weeks, a hip-joint apparatus with shoe attached, and perineal bands upon which the weight of the body could rest when the patient was walking, to permit the gluteal muscles to accommodate themselves to the pressure of the trochanter. One year later the shortening had increased to one and one-half inches; he moves the limb freely and strongly and has an unusual amount of power in rotating it; with the exception of a slight limp, he has entire control of the limb.

I have spoken of the increased distance of the trochanter from the median line in certain dislocations. I am not aware of this test having been published, but I have carefully examined it on the skeleton, and verified it often on the cadaver and on patients.

In making the examination, I place the patient on the floor or other unyielding surface; if the limb be dislocated, it will either not rotate freely, and this is the case in the usual dislocations where the integrity of the "Y" ligament is preserved; if it rotates freely, either the trochanter describes an enormous arc which is quite conspicuous, or the trochanter materially increases its distance from the median line; this applies only to dislocations in which shortening is one of the symptoms. The amount of increased distance of the trochanter from the median line is best determined by placing a large book against each trochanter, rotating both legs and measuring the distance of the book from the median line of the body. I would like to call attention to a ready method of accurately measuring shortening in injuries of the hip.

The method I have been in the habit of using is to first accurately mark both anterior superior spinous processes with an aniline pencil. It is sometimes difficult, where the ilium is much curved, to exactly determine the position of "the process;" under such circumstances, I mark the curve of the ilium for a couple of inches, then, as a radius to the curve, I draw a line at the process; if an error in the marking be made, it will be very conspicuous.

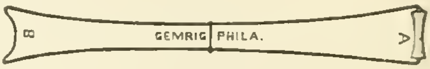
Now, having the anterior superior spine accurately marked, with the patient lying on his back on a flat, unyielding surface, with both feet at right angles to the legs, pass an inelastic cord around the hollow of the foot, and bring both ends to the corresponding spinous process. I feel satisfied that a very slight difference in length of the limbs can be readily detected by this means.

Dr. William Hunt alluded to the diminished value of accurate measurements in the treatment of fractures of the lower extremity, especially of the thigh, since the fact of asymmetry in the same person—irrespective of injury—had been found to exist in most cases. Where the shortening is due to overlapping, it is mostly appreciable by examination at the seat of fracture, and is of course to be corrected; but where the amount of it is fractional, and not apparent to the eye, and is only made evident by careful measurements, it may be fairly assumed that the patient was unsymmetrical before he met with the accident. Dr. Hunt spoke of a letter he had received from Sir James Paget, in which that distinguished authority acknowledges his dissatisfaction with the results of measuring, and rather relies upon his eye than upon the tape.

Dr. J. Ewing Mears remarked that he did not think epiphyseal separation of the head of the femur so rare an occurrence as stated by the author of the paper. The junction of the epiphyses to the shaft of the bone does not begin until after puberty, and is not completed until the twentieth year. It would therefore seem quite possible for separation to occur as the result of injuries to children, and, being unrecognized, would not be recorded. He was inclined to believe that in some instances of inflammation of the hip-joint, consequent upon injury, epiphyseal separation, more or less complete, had occurred.

SPLINT FOR SYNOVITIS OF WRIST-JOINT.

Dr. J. M. Barton exhibited to the Society a splint which he had been in the habit of using for some years in cases of synovitis of the wrist-joint; it is a light and convenient method of applying extension, permitting nearly entire concealment of the splint and some use of the fingers.



The splint is made of wire, is about eleven inches long and from one and one-half to two inches wide; it is placed on the palmar aspect of the hand and forearm, reaching from below the bend of the elbow to the metacarpo-phalangeal joints.

The upper extremity (B) is slightly indented to receive the adhesive plaster used in the counter-extension. On the lower extremity (A) the extending band plays. The extension is maintained by a piece of heavy nipper elastic, which is fastened to the upper cross wire at (B), and to the extending band after it passes over the roller at (A).

The extension is made by sewing a heavy kid-glove on the hand, cutting off all the fingers of the glove except that of the middle and ring fingers; these two are split down the back and retain their attachment only to the palm of the glove; they are passed over the roller and attached to the rubber extending-band, the upper end of which is attached to the upper cross-bar of the splint at (B). The counter-extension is made by two strips of adhesive plaster, each two inches wide and thirteen inches long, reaching from the wrist-joint over the upper extremity (B) of the splint and down again to the wrist; a light bandage from the wrist up keeps the adhesive plaster in place; the extending band, viz., the glove fingers, are attached to the rubber band by a piece of cord; the extending force is determined by the amount of tension of the rubber band, about one pound of pull being quite sufficient.

Dr. Barton presented also a patient with a splint on, that she had worn for the last five weeks; she had suffered from synovitis of the wrist for six months; she had been leeched, blistered, painted with iodine, worn a plaster dressing, etc., without effect; now, however, she is entirely relieved, the wrist is freely movable without any pain or tenderness, showing that this splint maintains an effective extension while worn. He does not claim any new principle, but only a more convenient apparatus than the usual one, where the elastic extension is maintained on a splint reaching several inches below the fingers.

SUPRA-HEPATIC ABSCESS WITH OBSCURE SYMPTOMS DURING LIFE.

Dr. Packard gave a verbal account of the following case:

Mr. F., æt. 36, was seized March 14, 1883, at about noon, with sharp pain in the right side of the abdomen as he was descending a staircase. The pain soon abated, and he walked home, about half a mile; but on the way had so violent a recurrence of the pain that he could scarcely walk. At about 1 P.M., when I saw him, he was lying on his bed in great agony, unable to move at all.

By the use of a large enema of Castile soap and hot water, an opium suppository, and the internal administration of chlorodyne in small doses frequently repeated, relief was given for some hours; but in the evening he had another severe attack. I now learned that Dr. George A. Rex had been consulted by him on account of dyspeptic symptoms several times during the winter, and at my request he took charge of the case along with me.

On the 15th, although he was in less pain, the symptoms of obstruction were unchanged, and the possibility that laparotomy might eventually be indicated was considered. Dr. Ashhurst, at my request, was also brought into the consultation, and agreed with us that an operation would be called for if other means failed to give relief. Leeches were applied over the seat of tenderness, and mercurial ointment; the anodynes were continued.

The leeching seemed to do him much good, and another enema brought away some fecal matter from the colon. After this the acute symptoms subsided, and after several days the bowels were moved without enemata. Yet he did not rally; his evening temperature continued to be above 102°, and his morning temperature over 100°; and his condition resembled enteric or typhoid fever. I attended with Dr. Rex until March 22d, when I ceased my visits until they should send for me.

March 31.—I was summoned in great haste in the morning, and found Mr. F. coughing up large quantities of excessively fetid pus, tinged with blood. He seemed very much prostrated, partly perhaps by the sickening effect of the odor of the expectorated matter. From this collapse, although stimulants and carbonate of ammonia were freely given, he never rallied, and death ensued in about three hours.

Autopsy, April 1, at 2 P.M. Body in ice; not much emaciation; no rigor mortis. An immense abscess, with walls lined with croupous lymph, was found occupying the space between the diaphragm above, the right lobe of the liver below, the suspensory ligament at the inner side, and the abdominal wall at the outer side. This had communicated with the right pleural cavity by an opening through the diaphragm at its posterior part. A good deal of sero-purulent liquid was contained in the pleural sac. Evidently there had been effusion from this serous membrane in addition to the pus.

The quantity of the liquid could only be approximately estimated, but seemed to be over a quart. The orifice by which the effused matters gained access to the air-passages could not be detected without a longer and more careful exploration than could be instituted.

On the first opening of the chest, the right lung was compressed, especially in its lower lobe; but the air subsequently entered this portion of the organ, and it resumed its normal appearance.

Between the duodenum at its very commencement and the parietal peritoneum of the right side, there was a close and firm adhesion, pulling the stomach out into an almost tubular shape; but beyond this there was no sign of any peritonitis other than that in the region of the abscess. All the other organs except those mentioned seemed normal.

STRANGULATED VENTRAL HERNIA, REQUIRING OPERATION.

Dr. Packard reported the following case:

Mrs. James, colored, æt. 57, had had a hernia a little above and to the right of the umbilicus since a severe confinement about twenty years since. It had often given her some trouble, but she had always succeeded in returning it herself, except on one occasion, some months ago, when it was out for three hours, and was then reduced by taxis by Dr. R. A. Cleemann.

Dr. Wirgman and myself were called to her at 4 P.M., March 21, 1883. The hernia had been out about four hours. She had no pain, no vomiting; but could not replace the mass. We tried the taxis, at first without and then with anæsthesia, but to no purpose. She was ordered a large enema of castile soap and water, and then an opium suppository; and ice to the tumor.

At 8 P.M., we saw her again, and found the tumor increased in size, still painless, though somewhat sore. A thorough attempt at taxis failing to produce any impression, the patient being etherized, it was decided to operate, which I accordingly did, with the aid of Drs. Wirgman and Horwitz, and Mr. Shober and my son, medical students.

I made a curved incision, embracing about one-quarter of the circumference of the tumor, at its upper and right aspect, and came of course at once upon the sac, after dividing the skin and fat. Reduction being still impossible, I opened the sac, and found a large mass of omental fat, beneath which was a double knuckle of bowel, quite purple, distended, and velvety in surface. I could not replace it until I had nicked the firm edge of the stricturing ring with a Cooper's knife, and not very easily even then, but as the stricture was relieved the bowel resumed its normal color. It was carefully washed with hot carbolized water, and after thoroughly replacing it, with all of the omentum that could be returned, I passed a silver-wire suture through the edges of the ring, and brought them together as closely as possible, twisting the wire six times from left to right, and allowing the long ends to hang out of the wound (traversing the sac, of course). The wound was then closed with four harelip pins, and a number of points of the interrupted suture. A carbolized water-dressing was then applied, and a bandage around the belly. Another opium suppository was given. The patient took the ether well, and at the close of the operation was in good condition.

March 22.—She has had during the night one or two sharp but transient attacks of pain.

23d.—Doing fairly well, although she has had at times some slight delirium; pains less severe; no marked tympany. One dozen leeches applied to belly, and afterwards a large wad of raw cotton. Tr. Aconit. Rad. with neutral mixture.

24th.—Harelip pins removed. Wound seemed to have adhered. Temperature 102°, otherwise better.

25th.—Bowels moved naturally.

27th.—Wound gaping, but not widely. A good deal of sloughing fat and areolar tissue coming away. Pulse and skin good; tongue slightly furred; some little pain in the night.

From this time on there was very little change, except for the better. The sloughs separated and came away, and the wound assumed a healthy granulating aspect, but still tended to gape so widely that

April 2.—I passed a large pin across through both lips of the wound, taking a very deep hold on each side, and applied a ligature around the ends, as in an ordinary harelip suture. This brought the edges quite closely together throughout, and she is in every other respects doing well.

The result of this case will be hereafter reported.

Dr. Wm. Hunt said that he was inclined to doubt the statement made in the books, that a purely omental hernia could give rise to as severe symptoms when strangulated as when the gut was involved. His disbelief arose from the fact that in the treatment of wounds where omentum projected, and also in some cases of hernia operation, we could safely treat the omentum most unceremoniously by purposely strangulating it with ligatures. He asked for an explanation of these facts.

His own idea was that in most cases there was a small portion of intestine involved, as even a portion of the wall of a gut might be pinched, and give rise to symptoms of strangulation.

The great mass of the kind of hernia under consideration being omental, a small portion of gut might not be recognized before reduction. In his own experience, he could not call to mind a case of purely omental hernia upon which he had operated. He once made a post-mortem examination upon the body of a young man who had died with the symptoms of peritonitis and strangulation, but in whom no tumor could be discovered. A portion only of the wall of the bowel was pinched and strangulated in the canal.

Dr. Hunt said he had seen cases of enormous collections of gas in the bowels in hernial sacs, but that these were generally of the reducible form. One case he remembered, where this was not so; the patient was an old and feeble man. The bowels were punctured in several places to let out the gas, but the patient died before they could be replaced.

Dr. Mears said in reply to a question by the Chair, that he had in one instance facilitated the reduction of a femoral hernia by the use of the hypodermic needle as an aspirator, withdrawing from the intestine gas and fluid.

Dr. J. M. Barton inquired of the Fellows if hemorrhage during the division of the stricture in the operation for strangulated hernia was not a bugbear and quite unusual, and what experience the Fellows had with hemorrhage under such circumstances, and what methods they had used to check it.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, June 6, 1883.

The President, Alfred Stillé, M.D., in the Chair.

Dr. S. Weir Mitchell read a paper on

THE RELATIONS OF PAIN TO WEATHER, STUDIED DURING ELEVEN YEARS OF A CASE OF TRAUMATIC NEURALGIA; BY CAPTAIN R. CATLIN, U. S. ARMY, WITH NOTES BY HIMSELF.

In *The American Journal of the Medical Sciences*, April, 1877, he said, I described the case of Captain Catlin, U. S. Army, and gave the results of his observations on the relation of states of the weather to his own pain. These studies, suggested by me and carried out with care, at length became of equal interest to the observer, and, with occasional advice, he has continued to keep notes, until the the record, with his comments, constitutes, in my opinion, a most valuable contribution to the strict science of medicine.

For full details of his case, I must refer to my essay, but it is needful here to make a brief statement explanatory, so that what he now says may be comprehensible without reference to the former record.

In August, 1864, Captain Catlin, then in perfect health, had his food crushed in battle by a round shot. There was no shock; the leg was amputated below the knee, and he was up and about in a month. Pain was felt early in the lost foot, and became severe within nine months.

I should perhaps state that, except as concerns pain, the observer is in admirable health, that his attacks are so definite as to coming and going, as to create little difficulty in this direction, and that from his former position as instructor in certain scientific branches at West Point, he is well qualified by training to pursue this difficult study. The weather reports of the Signal Office and his own, or the daily observations of others, have enabled him, from time to time, to relate these to his record of neuralgia, and by this method he has avoided the constant presence of daily thought as to what was about to happen in consequence of atmospheric changes. I may add that I never knew any man more free from unwholesome attention to his own ailments. Most of what I learned from our former study, still stands unaltered by this much longer record; but there have been some fresh and suggestive gains in the relation of pain to meals, to daily barometric changes, and to magnetic conditions.

The following is the report of the case for the past seven years, made by Captain Catlin:

For the year 1872 there were 1783 hours of pain (the records for 1873 and 1874 are incomplete); for 1875 there were 1892 hours; for 1876, 1790 hours; for 1877, 1794 hours; for 1878, 1591 hours; for 1879, 1535 hours; for 1880, 1567 hours; for 1881, 1405 hours; and for 1882, 1370 hours. From 1872 the annual amount of pain increased and probably reached its maximum in 1874, a year of high pressure, which, as we proceed, will be found to have some relation to the pain.

For 1875, we have the highest recorded amount of pain. The next year, 1876, the amount of pain fell off 100 hours, with a decrease of the mean annual pressure, equal to 00.021 of an inch, with corresponding increase of temperature. For the following year, 1877, the pain and pressure remained nearly constant and parallel, with some increase in temperature. For the year 1878, there was a remarkable lessening of 200 hours in the neuralgic amount, but by following up the barometric curve an equally remarkable fall is found. The annual mean of the barometer for the year (1878) was 00.068 of an inch below the mean of the previous year, and 00.067 of an inch below the mean for the eight years, the mean for the eight years being 29.916. From the low annual pressure of this year, we may almost infer a high annual temperature, which we do indeed find in the curve, and the Signal Bureau reported for the Middle Atlantic the temperature "above the average" for every month in the year except June. For the year the *number* of pain attacks and the *number* of storms remained about normal, but the *duration* of the pain attacks was shortened.

This law of relationship of low pressure and high temperature to amount of pain, and the number of attacks of pain, and number of storms will become more apparent when we come to the consideration of the quarterly and monthly distribution of pain and storm. Since 1878 the pain has diminished at the rate of forty hours annually; diminution being accelerated by a decrease of mean annual pressure and retarded (or actually held in suspension as in 1880) by an increasing pressure. Making allowance for the annual decrease of pain, there is a remarkable parallelism between the pain and pressure-curve. The yearly temperature bears the same relation to the barometer, as it was found to have in the monthly fluctuations. The total amount of pain for the eight years, ending January 1, 1883, was 12,944 hours, or nearly one-fifth of the time. The distribution of the pain was shown by a curve of the total monthly amounts for the eight years, from which it was readily seen that the winter months hold the advantage as pain-producers, and that for this period while the sun was north of the equator, there were 6,783 hours, against 6,161 hours, while it was south of the equator.

Of the quarterly amounts, the first quarter, beginning with the winter solstice, leads with 3,538 hours, followed by the fourth quarter at 3,245 hours; then the second, with 3,098, and the least in the third quarter (July, August, and September) with 3,063 hours.

Of the monthly amounts, March holds the lead, closely pressed by January, and in order of amounts follow: November, December, May, February, April, August, October, September, July, and June. The number of storms recorded for the eight years is 806, taken from the Signal Bureau Records.

Of this number 529 belong to the winters, against 397 for the summers.

The quarterly numbers, in like manner, correspond to quarterly amounts of neuralgia, and by a reference to the storm-curve there is shown a remarkable parallelism throughout with the pain-curve.

The average *duration* of each attack of pain for the whole time was 18.97 hours; but again we find average *duration* bearing a relation to amount of pain and number of storms.

The average for first quarter being 20.1 hours, for second quarter being 18.4 hours, for third quarter 17.9 hours, and for the fourth quarter 19.4 hours, which we see is directly proportional to storm and amount of pain. The average duration of pain was found to be greatest in February, 20.8 hours, one of the coldest, if not the coldest month, and containing probably the greatest barometric fluctuations of any month in the year.

Although the average velocity of translation of the winter storms be greater than the summer ones, owing to their much greater range and power, they are further reaching, and in consequence produce longer attacks. The hottest month of the year (July) gave the least average duration of pain, being seventeen hours.

This is a month of low average pressure and unimportant and minimum barometric fluctuations. By an examination of the curve of the mean monthly *number* of attacks, there is found an almost exact *monthly* parallelism with the pain and storm-curve, but the mean *quarterly* of the curve would not be as nearly parallel with the mean quarterly of the pain or storm, which shows that the number of attacks of pain is greater in proportion to the number of storms for summer than for winter. Many of the summer storms are difficult to trace, and some are not charted owing to their indefiniteness, but they are nevertheless pain-producers. For this reason it is believed that the relationship of the number of pain attacks to the number of storms is not as disproportionate as appears in the quarterly comparison of the curves.

Passing to the rain-curve, we find it in harmony with the pain and storm-curves, except for a few of the summer months. For these months, owing to the short and heavy precipitation of rain, and local character of many of the storms, the curve does not subordinate itself to the pain, storm, or even barometric curve.

Thus we see that rain-fall of itself is only relatively to be used as a measure for pain.

The barometric curve, as it swings almost a catenary from January to December, measures, with the storm-curve, much more accurately the ordinates of the pain-curve; and here we have reappearing in the quarterly monthly products of neuralgia the law already disclosed in the annual product of pain—viz., high temperature, low barometer, favorable for non-product of pain; and, in addition, minimum barometric undulations, favoring diminution of pain duration.

To determine the average distance of the storm-centre at the beginning of the pain attacks, sixty well-defined storms through ten consecutive months were taken, and it was thus found that the average distance was 680 miles, ranging from 200 to 1200 miles.

Storms from the Pacific are felt the farthest off, very soon after crossing the Rocky Mountains. Those which move along the coast from the Gulf of Mexico are associated with neuralgia not quite so intense, and are not felt, as a rule, until within the average neuralgia distance.

If neuralgia begins on a low and rising barometer, the ridge of high pressure between this and the coming storm-depression is narrow, and invariably broken down within seventy-two hours, and more frequently within twenty-four or thirty-six hours; and during this rise, coincident with the pain, the difference between the wet and dry bulb thermometer, instead of increasing, as is usual with this barometrical condition, sometimes actually diminishes, or increases for a few hours only, and then diminishes, showing increasing humidity.

When this pain and instrumental condition obtains, the coming storm depression will carry on its eastward side clouds and increasing moisture, and sometimes rain or snow, clear over the summit of the advancing high area pressure in front of it, holding an unusually high degree of relative humidity in the air on the high eastern slope of the high barometer area. These are the conditions when the pain attacks on the rising barometer. Its normal condition, however, is with a falling but it may be a high barometer, rising temperature, and increasing relative humidity.[1]

Should the pain be on during a day of intermitting rain, the pain takes an additional activity just before the increasing shower, and continues twenty to forty minutes; this will sometimes happen four or five times in twelve hours. Each little increment of pain seems to bear about the same relation to the showers, as the main attack bears to the storm.

It has always been observed that eating a meal when the pain is on intensifies it, and it is believed that it often hastens the attack. We should then expect to find some rise in the curve after each meal. This we do find at 9 A.M., which cannot be accounted for otherwise than that by eating at 8 A.M.. some of the neuralgia, which really belongs to 10 o'clock, has been prematurely developed, and so changed to 9 o'clock. Again, after the 1 o'clock meal, there is a decided rise in the number, *some* of which, at least, should be chargeable to the meal. It is also worthy of note that there is an ebb-tide in pain, just preceding the meals; not so marked before breakfast, partly, no doubt, because it is with me a little less regular than other meals, and partly because storms coming within neuralgia range during the early and middle sleeping hours, would not ordinarily arouse their victim, but would strike in the morning, as the sleep became less profound.

This, doubtless, is the cause of the rapid rise in the curve between 5 and 6 A.M.

In support of this statement of the respect which a storm may have for its neuralgic subject, it may be added, that if the pain is on when the patient falls asleep, and he is aroused or awakens during the night, he will find himself free from pain; but if he should move about, or stay awake fifteen or twenty minutes, the pain is renewed, unless in the mean time the neuralgia time has expired.[2] At 11 P.M., the average number of attacks is not one a year, and from this time until 6 A.M., there is great immunity from *onsets* of pain.

With regard to the prominent and remarkable feature of the curve on the 11 A.M. ordinate, it cannot be positively stated why the pain has shown this great partiality; but there are some reasons which may be of interest to state. We have found that the years of high mean annual pressure gave high pain readings. We have also found that neuralgia in its relation to storms was not averse to a high barometer, but usually attacked on a falling barometer with rising temperature or increasing humidity.

---

[1] See same case in American Journal of Medical Sciences for April, 1877, p. 21.

[[2] This is true in regard to most pain, and may be within the experience of many men; we fall asleep suffering, but awake without pain, even if the cause of pain remains. A brief period of being awake seems to be needed, in order that the cause may become active. Sleep is a true anæsthetic.—S. W. M.]

The pain in its relation to the diurnal change of the barometer occupies a position analogous to what we found it in its relationship to barometric movements accompanying storms—that is, high barometer, and on its fall preceding the storm, with increasing humidity and temperature. For the eight hours from 9 A.M. till 4 P.M., during the daily fall of pressure, there are 610 onsets against 346 for the remainder of the day, or sixteen hours. The maximum amount of vapor in the air from 2 until 6 P.M., increasing from before sunrise till just before sunset. We have then for the greatest daily neuralgic period a corresponding falling barometer, increasing vapor and temperature, with the analogous condition complete.

In regard to the 11 A.M. period, there are some other points of interest.

By a reference to the diurnal changes in the magnetic curves, we find: in the declination curve two maxima and two minima daily. The principal maximum occurs at 8 A.M., and the principal minimum at 2 P.M. From this minimum in its progressive movement there is a slight undulation in the curve about 10 P.M., giving rise to a subordinate maximum with another minimum following two hours later near the mean of the curve; from this we reach the principal maximum at 8 A.M.

In the inclination curve we have also two maxima and two minima. The leading and principal feature of this curve is its morning maximum which occurs between 10 and 12 M., probably 10.45 or 11 A.M. A subordinate maximum about 10 or 11 P.M. There is a minimum between 5 and 6 A.M., and another about 5 P. M.

Each of these maxima has a corresponding minimum in the horizontal force. So also the minima in inclination correspond in like manner to maxima in horizontal force. Owing to the great and precipitate change in declination between 8 A.M. and 2 P.M. with the pronounced occurrences in inclination and horizontal force at or close to 11 A.M., may we not with some reason suspect these as active agencies in constructing the 11 A.M. neuralgic period?

The two o'clock period is one connected with the highest temperature and the maximum wind force of the day. It is believed that hours of maximum and minimum rain-fall have some influence on this curve. The British Government[1] has published some observations which, although not conclusive, seem to show that there are two daily maximum rain-falls, one at 7 P.M. and one at 5 A.M.; also two minimum periods, near noon and midnight. It is believed, further, from sensible impressions and limited observations, that solar and earth's radiation have an influence on the daily character of the neuralgia, and, if fully studied, would assist in interpreting some features of the curve not fully understood. With complete record of *local* meteorology, including radiation, there seems but little doubt that all the details of the diurnal curve could be demonstrated. There is one additional fact in connection with the onsets of pain which seems curious, and that is the period of drowsiness and sleepiness which precedes the attacks from one to five hours. This rule is not invariable, but is general.

For the seven years from November 7, 1875, to November 17, 1882, there have been nine neuralgic attacks of great and unusual power. These were characterized by pain in nerves not usually attacked. The ordinary neuralgia in the foot is of the burning and boring kind, with twitchings of nerves in the stump, while in the extraordinary attacks, in addition to the pains as above named, we have the intense stabbing variety, with a much higher degree of the convulsive tendency. Accompanying each of these attacks, except the last, we have the pain period dominated by more than one storm in six out of the nine attacks, and in *every* case the low barometric depression was of unusual and enormous extent. The attack of November 7, 1875, began at 7 P.M. and lasted until 2 P.M. on the 8th, and was undoubtedly mainly under the influence of storm No. IX. (as charted by Signal Bureau), while passing from Savannah to a position off Cape May. The depression of this storm "became more extended as it advanced, with increasing velocity; the region of precipitation including the entire Southern and Middle States." By 7 P.M., closely following this attack, was an attack of the regular neuralgia, which lasted 27 hours, to meet the requirements of Storm VI.; and this is a general rule, that these unusual attacks are followed by the regular neuralgia.

The attack of September 29 and 30, 1876, was under the influence of storms IX. and X. of that month. The weather report of the Signal Bureau says: "The map of the 29th, 4.35 P.M., shows that at that time a very large area of low pressure must have existed in British America on the south and east of James Bay, the southern end of which extended southward until on the morning of the 30th, the barometer was below 30 inches everywhere east of Lake Superior. The winds of Georgia and Indiana during this time were from east to southeast.

The attack of April 3, 1877, belongs to Signal Bureau Storms, Nos. II. and III. "An extensive area of cool northeasterly winds prevailed throughout the Gulf States, Ohio Valley, and Lower Lakes." In Middle Atlantic States, northerly winds moving to east with increasing cirrus and cirro-stratus cloudiness. The general depression extended over a large area. The attack of August 3, 1877, belongs to storm marked II. on monthly report. "There was a marked fall of the barometer in the Southern Atlantic States on the 2d, which district was then, in all probability, in the N. W. quadrant of an extensive depression." "N. E. winds prevailed from New York to Florida." The neuralgia attacked at 11 A.M., and at this time in the direction of the storm S. E. there were increasing cirrus and cirro-stratus with bunches of cumuli lower. This storm "united with No. I. over the St. Lawrence. Later in the day thunderstorms in northwest to northeast." The attack of May 31, 1879, corresponds to the extensive storm of No. XV. of Signal Bureau Report for the month.

The attack of October 16th corresponds to Storms IV. and V.; the former coming up the Mississippi Valley unites with the latter from the North Pacific, in Lake Michigan.

The attack of April 10, 1881, is related to Storm III., including Storms II. and IV. as described by the Signal Bureau Report.

It was observed on this occasion, as is frequently the case with this variety of pain, as also in the ordinary kind, that there was a cloudless sky with a delicate milky sheen in the atmosphere, more marked around the horizon. This milky veil becomes more opaque, and the first pronounced cloudiness will be small patches of cumulus, at lower elevation than this hazy appearance. These are storm indications, and favorable for the production of pain. This was the stabbing variety, as in each case here described, added to the other varieties, and was active between the heel and left side of foot.

The attack of February 11, 1882, corresponds to Storm VI. as marked in report of Signal Bureau. At the time attack began, the centre of the storm was six hundred miles westward. This was of wide lateral range and is the only one charted for the month as coming from the Pacific coast.

For the attack of November 17, 1882, Prof. Carpmail,

---

[1] Prof. Loomis, in Amer. Journ. of Sci. and Art, July, 1875.

Superintendent of the Toronto Observatory, reports more than ordinary declination and force disturbances from the 10th, including the 16th, when "they evidently showed signs of a coming storm." The magnetic storm set in at 5 A.M. on the 17th, and continued with great and intermitting force all day and night, and did not quiet down till midnight of the 18th. The report says, referring to the evening of the 17th, "that the force (horizontal and vertical) instruments, which in the early part of the storm showed a general decrease, now showed an increase, and between 7 P.M. and midnight, the lights several times travelled to both ends of the paper; the bifilar going off a number of times." The extremes of declination were reached easterly at 6.25 P.M., and westerly at 9 P.M. On the 19th, the magnets were disturbed, the disturbances being greatest between 11 P.M. of the 19th and 4 A.M. of the 20th. Many of the force movements were swift and rapid, the last movement of importance occurring at 9.20 P.M. on the 20th. Brilliant auroras reported on the 17th. This storm was unusually severe in England with brilliant aurora on the 17th. The disturbances here probably did not differ materially from those reported from the Toronto Observatory.

There was from the 10th instant, great unrest in all the nerves of the foot, such as feelings of twitching and slight burning, and at no time did the agitation touch the zero line of no pain. At 2 P.M. of the 17th the intense stabbing pains set in and reached the maximum power from 4 to 7 P.M. They continued, however, with great force until 5 A.M. on the 18th, and intermitting and less strong fits of torment were felt till evening; then a period of rest occurred until 9 A.M. of the 19th, when a severe attack of the regular neuralgia set in, with more or less burning and twitching pains throughout the foot, which lasted more than thirty-one hours, and finally went off on the evening of the 20th. The intense neuralgia of the 17th seems connected with the magnetic storm of the 17th, for there was no storm of barometric depression charted by the Signal Bureau within neuralgic range for this date. The last storm preceding this time was storm No. II. which started from the Pacific on the 8th, and for which there was a regular neuralgia on the 9th and 10th. The next storm was No. III., which originated in Texas on the 18th, and the attack of pain of the 19th and 20th was for this storm aggravated by the magnetic condition of these dates. It is firmly believed that neuralgia accompanies intense auroral periods, but owing to their rare occurrence, it cannot be said that the proof is conclusive. The conjunction of the two seems too frequent for mere coincidence.

In regard to treatment, etc., I can say but little. There has been no treatment in a medical way of late. I have had good health, take a great deal of exercise, but in a rather irregular way; my appetite is always good, and I sleep well, except when the disturbance of neuralgia interferes. For the year 1878, in which occurred the greatest diminution of pain for any year, there was the greatest physical weight, reaching one hundred and ninety pounds. Physical exercise, nutritious food (have found milk most fattening of all) and light, aggreeable occupation, are, I found, the best regimen for this neuralgic subject.

Dr. Harrison Allen, then presented

A CLINICAL STUDY OF THE CRANIAL NERVES.

The cranial nerves at their nuclei of origin and in the course of their intrinsic fibres may be involved in diseased action. It would seem to be more than a coincidence that the nuclei of the ninth, tenth, and eleventh nerves are arranged in a definite series, forming the trineural fasciculus; and that the nerves themselves are associated in function. But this line of reflection is useless when applied to the nuclei of the sixth and seventh nerves. These nerves appear to have no function in common, and yet they arise, in part at least, from the same nucleus. In their range of variation they have no relation with one another; nor in any animal known to the writer does the sixth nerve spring from the facial trunk, but always (in variations from the human type) from the third. The third, fourth, and sixth nerves are naturally associated; but no reason is assigned for the withdrawal of the nucleus of the sixth from the mid-brain, where the nuclei of the third and fourth nerves lie, to the hind-brain, where it is in association with an alien, namely, the seventh. Associated paralysis of the third, fourth, and sixth nerves is common; but paralysis of the sixth and seventh is rare.

The different symptoms of encranial paralysis may be assigned to one of two groups of causes, viz., to pressure, or to injury. Pressure may affect a nerve remote from the origin of the pressure. A tumor of the cerebellum, for example, has been found to be associated with a facial palsy, although neither the nuclei nor the intrinsic fibres of the seventh were involved. Clinical reports do not discriminate between the direct effects of injury and the indirect effects of pressure. Until the influence of this pressure is known and in each case eliminated, the study of localization of diseased action in the brain must remain in an unsatisfactory state.

Among the localities in which the effects of local pressure have been determined may be mentioned the pontal portion of the medulla oblongata, at which place the inferior vermiform process of the cerebellum may press against the nuclei of the cranial nerves there situated; the third ventricle, where, from a tumor in the corpora quadrigemina, or the pineal body, the lymph of the lateral and third ventricles accumulates in these chambers, and presses downward, notably at the floor of the third ventricle and the lamina cinerea; the region of the hippocampus in the descending horn of the lateral ventricle, which may be distended by the accumulation of fluid in senile states of the brain. Even where the fluid from the larger ventricles is conceived to pass freely along the iter to the fourth ventricle, it is fair to suppose that if this fluid is excessive in quantity, undue pressure will be exerted on the walls of the iter, and that some instances of paralysis of the third and fourth nerves might have their origin in this way.

The causes due to injury of the nerves are of two kinds—primary, when the lesion is due to the direct pressure of a tumor, or a clot of blood; and, secondary, when it is caused by the deteriorating influence of a tract of degeneration in the neighborhood.

Of the first-mentioned, that is to say, of the effects of primary pressure, there is abundant clinical evidence—indeed, it is the only evidence which is indubitable. Of the second, it must be acknowledged that the evidence is purely hypothetical; and as far as the writer knows, no case can be adduced in its support. It may be more than a coincidence that the study of frontal (transverse) sections of the medulla and of the stem of the brain shows that the nerves most commonly paralyzed in hemiplegia of encephalic origin are those whose intrinsic fibres lie in the immediate neighborhood of the pyramidal tract, as this has been defined by Türck, Flechsig, and Charcot. Thus the third, sixth, seventh, and twelfth nerves would be easily influenced by diffusion from the tract of degeneration, while the remaining nerves of the series would escape.

Dr. Charles K. Mills said that the subject touched upon by Dr. Allen was one of great interest to him. With reference to the effects of pressure upon the nuclei of the cranial nerves, he said that, without doubt, some extraordinary and apparently inexplicable affections of cranial nerves were due to such pressure. Intraventricular effusion, however, such as occurs in hydrocephalus, was not likely to produce local paralysis or spasm, because, owing to the free communication between the various ventricles, unless such effusion took place suddenly, the nerve-centres and conductors seemed to accommodate themselves to the pressure, which was distributed over a large area and over nearly all districts alike.

Those cranial nerves which had the greatest peripheral exposure, and the longest and most tortuous course in bone and membrane (the facial, oculo-motor, etc.) were most liable to be affected by syphilitic, rheumatic, gouty, and other similar diseases.

He supposed that the facial and abducens were so often affected independently, because paralyses of these nerves were usually peripheral; the lesions causing them being situated not only beyond the nuclei, but commonly beyond the superficial origins of these nerves. Besides, some authorities claimed separate, although near, nuclei for the sixth and seventh. He had, however, seen more than one case of conjoint paralysis of the abducens and portio dura, presumably due to degeneration of the combined nuclei.

He recalled one case, which he did not think had been put on record, but was well worthy of being detailed in connection with a study of these affections of cranial nuclei. The patient was sent from the South to the Hospital of the University of Pennsylvania by Dr. John Guitéras, and was the victim of complete double oculo-motor paralysis. Associated with this was advanced atrophy and paralysis of both upper extremities. Here he believed the lesion to have been bilateral degeneration of the nuclei of the cervico-brachial nerves, and also of the oculo-motor nuclei. One of the strange features of the case was the fact that the cranial nuclei between oculo-motor and cervical regions (those of the pathetic, trigeminal, facial, abducens, glosso-pharyngeal, etc.) had escaped.

Dr. Mills said, also, that the present was perhaps a good opportunity to put on record an observation on cerebral glosso-labio-pharyngeal paralysis. It is well known that this affection is usually attributed to degeneration of the cranial nuclei; in fact, it is often called "bulbar paralysis." A patient presenting the oral, labial, lingual, and pharyngeal symptoms of this disorder, had died about two years before at the Philadelphia Hospital. Examination showed no lesion of pons or medulla. Along the outer border of both lenticular nuclei, and extending into the external capsule and claustrum, were long, narrow, and somewhat irregular areas of degeneration; softened or broken-down districts surrounded by walls of harder, darker tissue. Kirchoff and others had since reported similar cases, but up to the time of making the observation he had never seen such a case reported.

In conclusion, he said that Dr. Allen had discussed the probability or lateral diffusion of descending degeneration. He thought this lateral extension of degeneration more likely to occur at the top of the system than in the motor tracts, from cell to cell in the central zones rather than from fibre to fibre in the conducting columns. He confirmed Dr. Allen's remarks with reference to the practicability of naked-eye observations of degenerated areas and tracts; and spoke of the brain of a hemiplegic negro murderer, presented by him to the Philadelphia Pathological Society, which showed atrophy of the right cerebral and of the left cerebellar hemisphere, and a connecting tract of degeneration through the pons.

Dr. W. W. Keen referred to one point mentioned by Dr. Allen, the question of the common nucleus for the sixth and seventh nerves, and called attention to an extremely rare and interesting

CASE OF CONGENITAL AND BILATERAL PARALYSIS OF THE SIXTH AND SEVENTH NERVES.

This case he had been requested to see by Dr. George C. Harlan on account of its bearing on the artistic anatomy of the face. Dr. Harlan had reported it in full in the *Trans. Amer. Ophthal. Soc.* for 1881. Dr. Keen had had his face photographed as well as copies taken of a photograph in childhood. Unfortunately the existence of the latter was not known until the more recent photograph had been taken, or the point of view would not have been reversed.

At the date of examination he was eighteen years old. His expression in the second photograph it will be seen had scarcely changed at all from that of the earlier one. His face had simply enlarged. The condition had existed from birth. Not a muscle of the face responded either to the will or to the battery. The corner of the mouth could be slightly depressed by the platysma. Salivation was normal; hearing was good; speech perfectly intelligible, and only affected by the want of control over the lips; taste and sensation in the tongue were unaffected.

There was double internal strabismus; the cornea was slightly dull; vision O.D. $\frac{20}{126}$ and O.S. $\frac{20}{c}$; not improved by glasses; the impairment was chiefly due, apparently, to constant epiphora; ophthalmoscopic examination unsatisfactory, but the fundus seemed normal. Fixation was with the macula in each eye. No diplopia.

The absolute, bilateral, and congenital absence of function of the sixth and seventh nerves, without any involvement of the chorda tympani, points clearly to defective development of the nucleus common to the sixth and seventh nerve, and tends to confirm the assertion of Sapolini (*Amer. Journ. Otology*, Oct. 1881, p. 312) of the differentiation of the chorda by origin from a distinct nucleus as a thirteenth cranial nerve.

In reply to the discussion elicited by his remarks, **Dr. Allen** thought that the manner in which the effects of locomotor ataxia are witnessed in the spinal cord confirmed his own impressions with respect to the manner by which diffusion can take place about a tract of degeneration. It is well known that in this disease the central ravages are not confined to the postero-lateral column in which they are initiated, but extend to the postero-median column, and may even pass over the postero-median fissure. A yet more striking instance is seen in the experiments of Gudden, who extirpated the eyes of rabbits, and observed the change that took place in the optic tracts. It was found that the paths of degeneration were not limited to the visual lobes of the corpora quadrigemina, but had involved adjacent structures by diffusion. The effects of degeneration seen in the peripheral nerve trunks, where they were strictly limited by reason of the medullary sheaths, would not serve as precedents for the localization of similar effects in the central nervous system, where such sheaths are often absent.

THE PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday Evening, May 10, 1883.

Vice-President, F. P. Henry, M.D., in the Chair.

TYMPANIC CARIES PRODUCING SUB-DURAL ABSCESS OPENING INTO THE LATERAL SINUS.

Dr. Davis presented a specimen with the following history: Neil D., aged 18, was admitted into Prof.

Agnew's ward in the Pennsylvania Hospital with the following history: When he was five years of age, he had measles, and since that time he has had suppuration of the right middle-ear. It discharged at intervals. Two weeks previous to admission he had acute pain in his right ear, and a week later it began discharging. He had severe headache ever since he was first attacked. The pain was situated principally towards the front, but existed also towards the sides of the head. The discharge was profuse and offensive. He was emaciated, his face was haggard, pale, with a slightly yellowish tinge, he had an anxious expression of countenance, and altogether looked very badly. His mother says that this change occurred entirely during the two weeks prior to admission. The ear was cleansed and astringents applied; the discharge ceased in about six days. Bromide of potash failed to relieve the headache, but morphia hypodermically gave temporary relief. He held his neck stiff with the head slightly drawn back. This increased as the disease progressed. He had nausea, and later vomited large quantities of greenish-black fluid. Three days after entrance, the pains extended down the spine and into the legs and to the under side of the arms. On the fifth day after his admission, the headache and pains in the lower extremities were very severe. The discharge had almost ceased. His temperature rose to 102.5°. An ice-cap afforded no relief. On the eighth day he died.

The following statement shows the range of temperature and pulse from the date of entrance into hospital (9th), until his death:

	Temperature.		Pulse.	
	Morning.	Evening.	Morning.	Evening.
9th, . . .	100°	103°	62	86
10th, . . .	101.5°	101.5°	70	96
11th, . . .	98.5°	102.4°	66	80
12th, . . .	99.5°	100.8°	68	84
13th, . . .	102°	102.5°	84	88
14th, . . .	102°	105.4°	100	102
15th, . . .	103.5°	102.5°	106	104
16th, . . .	101.6°	102°	136	114
17th, . . .	99°	100°	112	108

His bowels moved regularly; they were not constipated.

Post-mortem examination, made twenty hours after death.—Skull was very thin at all points. Dura mater apparently normal. Marked congestion of the arachnoid and pia mater, more so on the right side. No evidences of thickening or other disease. Brain normal. No excessive cerebro-spinal fluid.

Region of Right Ear.—Beneath the dura mater covering the petrous portion of the right temporal bone over the middle and internal ear, there was an abscess about an inch long. It communicated by a small opening with the tympanum. At its opposite extremity it opened into the lateral sinus. This was filled with pus from the point of opening to within two inches of the torcular herophili. These two inches were filled with a soft black clot. Below the point of opening to the jugular foramen, there was thick pus and a partly decolorized clot, much firmer than the one extending in the direction of the torcular herophili.

Remarks.—The congestion was active, not passive; it was most marked on the surface of the brain. The large veins were not distended, and there was, consequently, no excess of fluid. The patient's mind was clear to the last. The most marked feature of the case was the emaciation, which was very rapid. An interesting point in connection with the case is the cause of death. It seems to have been due to the entrance of pus into the circulation; in other words, it was probably a case of true pyæmia. He had two marked symptoms of pyæmia—the sallow countenance and the rapid emaciation; besides these he had vomiting. He never had the slightest chill, or the sudden rise and fall of temperature, both so marked in cases of pyæmia. Sweet breath and any external abscesses or lung affection were also absent. I was unable to examine the other organs.

SPECIMENS (LUNGS, HEART, AND KIDNEYS) FROM A CASE OF BRIGHT'S DISEASE.

Dr. Frederick P. Henry presented the organs from a typical case of chronic parenchymatous nephritis. The kidneys are slightly enlarged, extremely pale, with marked arborescent vascularity of the surface and with non-adherent capsules. In fact, they represent one of those instances in which the gross appearance suffices for diagnosis. The heart is slightly enlarged, its left ventricle dilated, its walls fatty, and its valves competent. This heart gave rise to no murmur, strictly so called, but did produce in typical degree the sound called by Bouillaud and Potain the *bruit-de-galop*. Potain considers this sound to be diagnostic of interstitial nephritis, but Dr. Henry said that he had invariably encountered it in cases of Bright's disease in which the parenchymatous affection was predominant. The lungs are congested and œdematous throughout. The pleura is greatly thickened on both sides and the pleural cavities abolished, with the exception of the diaphragmatic portion of the right side, which contains a small amount of fluid in the shape of a number of serous-containing loculi. The cause of death was œdema of the lung, and the interesting question arises as to whether œdema of the lungs, which is so common an event in cases of Bright's disease, may not be favored by the obliteration of the pleural cavity, also commonly present in these cases: or, in other words, and conversely, whether the pleural cavity may not serve as an outlet for effusions which, but for its presence, would infiltrate the lung parenchyma.

Although his attention has not been specially directed to the point which he has just raised, and therefore he has no cases other than that just reported to bring forward in its support, he thinks he can state, in general terms, that before œdema of the lungs occurs, in cases with open pleural cavity, that cavity contains a considerable quantity of fluid. That is to say, that its capacity to act as a drain to the lung tissue is exhausted, and it does not at all follow that, for this result to be produced, the pleural sac should be *distended* with fluid. In fact, it would seem that a moderate amount of fluid in the pleural sac may be sufficient to exhaust this conservative power, and this amount varies with the state of the pulmonary circulation.

The view just advanced is in complete harmony with what we know of the physiological function of lymph spaces, among which the large serous sacs are reckoned. The last volume of *Transactions* (Vol. X.) contains a paper upon pleural effusions, in which Dr. Henry argued that any cause which interfered with a proper expansion of the thorax would lead to congestion of the pulmonary capillaries, thereby favoring pleural effusion. The results of capillary congestion vary in different systemic conditions. In Bright's disease, owing to the altered state of the blood, the result is œdema, that is, a serous infiltration of lymph spaces. Effusion into the serous investment of organs such as the lungs and heart, is conservative so far as concerns the parenchyma of these organs. The practical result of these considerations is that œdema of the lung, in cases of Bright's disease, is favored by pleuritic adhesion; and, secondly, that œdema of the lung may, perhaps, be averted by the timely performance of paracentesis.

MYXOMATOUS TUMOR OF THE SUBCUTANEOUS CELLULAR TISSUE OF THE CHEST.

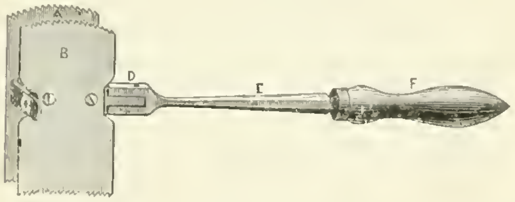
Dr. MacConnell presented the specimen, which was removed by Dr. Allis at the Jefferson Hospital Clinic one week ago. The patient was a man, aged sixty-three years, who stated that six years ago he had been struck on the side of the chest by a box at a spot corresponding to the site of the tumor. The growth commenced shortly after this traumatism, and at the time of operation was of the size of a pecan nut. The microscopical appearances were somewhat the same as those presented by the specimen presented for him by Dr. Nancrede in December, 1882. The present specimen very beautifully illustrates the transitional stages of the fœtal development of bloodvessels, such as budding, etc. Abundant yellow elastic tissue is also seen. The cells are but faintly stained with picro-carmine, owing to the highly refractive substance of the growth (mucin), rendering the coloring of the nucleus indistinct. Dr. MacConnell thought that the apparent rarity of similar growths was due to the use of alcohol for hardening purposes. If such a reagent be used, only the appearances of a young connective-tissue growth will be detected.

NEW INVENTIONS.

DOUBLE-BLADED SAW, FOR REMOVING PLASTER CASTS.

By A. H. MEISENBACH, M.D.,
of St. Louis, Mo.

The instrument consists of two blades (A B,) a shaft (D E), to which the blades are attached, and a handle (F).



The shaft consists of a square part (D) and tapering part (E). The square part D is made in two halves, one half stationary, the other half hinged to stationary part, as shown in Fig. The movable half is kept in position by a spring (C), which has a notch cut in it, and retains the part in position. The blade (A) is attached to the stationary part of the square part of the shaft by two screws, and the blade (B) is similarly attached to the movable part.

The object in constructing it thusly is to allow opening apart of the blades, so as to facilitate cleansing. The blades are 1¾ inches wide, and 2¼ inches long. One side of the saw blade is rounded, the other square; with its rounded side it is possible to saw in angles, as the elbow, over the ankle, etc. The space between the blades is ⅜ inch; the length of shaft is 6½ to 7 inches. The instrument may be made larger if desired; but I find that if the space between the blades is increased, the strip sawn out is somewhat harder to chip out than if it is of the size above described. The saw can be very easily constructed by any instrument maker.

With this instrument I have been enabled to remove plaster of Paris casts much easier and quicker than with anything I have tried. A great objection to plaster shears is that they cannot be used in all situations, and also that there is often not sufficient space between the limb and cast to efficiently insert them, and also that the cutting of the blades is interfered with by clogging by plaster. The saw can be used in all situations, such as bend of elbow, ankle, etc. The mode of using is as follows: Saw down the entire length of the cast to a depth of say ⅓ to ½ inch, then remove the strip thus sawn out with a chisel or any suitable instrument; continue this operation until the entire cast is sawn through, or the portion of cast is reached that is not completely saturated with plaster, and which can readily be cut through by a knife or scissors. When the cast is cut through, it can be removed in the ordinary way, or if it is not desired to remove it, a bandage can be put around it, and thus it can be drawn together, thereby making the cast fit tighter until it is desired to remove it. It is often desirous not to remove the cast, only to tighten it, and for this purpose the saw acts admirably.

CORRESPONDENCE.

CARBOLIC ACID POISONING.

To the Editor of The Medical News.

Sir: A few days ago I had a chance to study the symptoms of carbolic acid poisoning in two children, the one, a boy of 8 years, and the youngest, a girl of 5 years. They were both troubled with *Oxyuris vermicularis* (thread-worm), and I had prescribed carbolic acid, twenty drops, to be added to a pint of water, and used as an injection. But on account of some misunderstanding, the mother had added a large teaspoonful of the acid (which contained by actual measure seventy drops) to a pint of water. She had given both children the above injection about half-past 7 o'clock A.M., and in about five minutes after the administration of the injection, they both fell asleep, and slept for about twenty minutes. After this they awoke, got up from their bed, talked constantly and incoherently, walked about the room in a very restless manner; very soon their gait became uncertain and unsteady, till, unable to maintain an erect position, they fell upon the floor. They were entirely unconscious, their eyes had a wild and vacant stare, and pupils were much dilated. Their breath was charged with the vapor of carbolic acid. The forehead of both children was hot, extremities, however, were of a normal temperature; the skin was covered with perspiration. The pulse was full and frequent. Even after they had been put to bed, they showed constant muscular agitation, and it appeared that they might have convulsions any moment. They did not appear to suffer any pain.

About 9 o'clock A.M., they became more easy and quiet, the muscular agitation gradually subsided, and they fell into a comatose condition from which they could be roused only with difficulty; when they would open their eyes, still having the same wild and vacant stare. During this state, respiration was somewhat laborious and diminished in frequency. About 11 o'clock A.M., the boy, when roused, appeared to be conscious, but immediately relapsed into a somnolent state.

About one hour later, the girl regained consciousness. Soon after that they commenced to vomit and vomited more or less all day. After that they recovered rapidly.

In regard to the treatment, I wish to add that immediately upon my arrival at the house, I washed out the rectum with an injection of water, soap, and castor oil, and not knowing an antidote for carbolic acid, I administered five drops of spts. aeth. nit. every hour, with the view of eliminating the poison by the kidneys.

Respectfully yours,
H. H. Vinke, M.D.

St. Charles, Mo., July 5.

NEWS ITEMS.

NEW YORK.

(*From an Occasional Correspondent.*)

The Code of Ethics in New York.—The warm weather does not seem to impede the activity of the National Code supporters, who have kindly given the writer access to their papers, which show a steady increase in favor of the American Code. The writer's attention was attracted by a letter lately received, and on inquiring whether others to the same effect had come, was handed a package from which abstracts were made. It soon became evident that many who had hastily given countenance to the New Code, saw that they had made a mistake, and frankly and manfully withdrew their support from the New Code, and transferred it to the National Code.

A few examples are given below.

**, ** County, July 2, 1883.

"I examined, last week, a circular containing the honorable names of ***, ***, and a number of worthy medical men, who, it seems to me, wish this war stopped by our yielding to the demands of an uneducated, public opinion, and recognize irregulars, etc., as fit for us to consult with on issues of life and death intrusted to our discretion. . . . I have had little time to investigate the question, and have taken much "on faith." I thought, by that array of eminent names, this was no doubt the judicial vote of the majority of our honorable profession, and determined to be reconciled to it, though it was antagonistic in a high degree to my wishes. Therefore it is that I signed the (New Code) paper.

"I have just opened another circular with a list ot names of physicians of New York City who wish the National Code of Ethics upheld. . . . When I see in this circular the names of ***, ***, ***, and hosts of others whom I esteem, I feel impelled to write this. I submit to the wisdom of the majority. My decided wish is for the success of the regulars in every contest with ignorance, bigotry, dishonesty, and trickery, whether with the laity or amongst professional quacks.

"Signed, ***, M.D."

**, ** County, April 23, 1883.

"For the National Code. Reconsidering my first opinion.

"Signed, ***, M.D."

**, ** County, May 22, 1883.

"I reported, a few days ago, in favor of the 'New Code.' After considering the matter more fully, I wish to place myself on the opposite side, and uphold the National Code.

"Signed, ***, M.D."

New York, April 26, 1883.

"I was, unfortunately, absent at the last meeting of the County Society when the vote was taken on the Code question. Since then, at the solicitation of a friend, and from a superficial understanding of the case, I signed one of the forms which are being circulated by the 'New Code men;' but from the statement presented by your circular I desire to state most emphatically that I favor the National Code.

"Signed, ***, M.D."

A gentleman, whose name also appears on the "New Code" list, says (April 25, 1883), "most decidedly the Old Code; many more have so decided."

Another says (June 3), . . . "be kind enough to omit my name from any list of subscribers to the 'New Code.' I believe I signed a postal card to such an agreement, but would like to reconsider the matter."

Such cases as the above might be multiplied to a greater extent than space in these columns will permit.

In the defence of their cause, the National party have shown much foresight, thoroughness, and activity, as well as a masterly grasp of the situation, and have made more progress in the last five months than have the "New Code" party in as many years. They began work in the very "camp" of the enemy, and were victorious as soon as organized. Their canvass has been eminently successful, simply because they have sought to learn the sentiment of the whole profession on all sides. The three questions have been uniformly asked, "Are you for the National, the New, or no Code?" Thus giving every one an opportunity to put himself on record. They say that the canvass will be continued until every physician in the State has answered who has a right to be heard. The majority in the State at large is still on the increase, as well as that in the State Society, which is a majority of the entire membership.

Among the warm advocates of the National Code (outside of the city, but in the State of New York) are E. M. Moore, President of the American Surgical Association, and Langworthy and Hovey, of Rochester; Didama and Van De Warker, of Syracuse; Miner, Rochester, and Gay, of Buffalo; Bontecou, Seymour, and Ferguson, of Troy; Hutchison, Squibb, and Segur, of Brooklyn; Churchill, West, and Gray, of Utica; Squire, of Elmira; Hyde, of Cortland; Palmer, of Ontario; Govan, of Rockland; Reynolds, of Saratoga; Wise, of Seneca; Dolson, of Steuben; and hosts of other representative men, well known in and out of the State. These and many others, together with the New York City forces, are the men who will cope with the opposition, and who are determined to uphold the National Code of Ethics, and insure its reënactment in February next.

BROOKLYN.

(*From our Special Correspondent.*)

Dr. Thomas Gallaher, not Gallagher, as generally written, who has recently received a life-sentence as one of the leaders in the dynamite conspiracy at London, is a regularly educated physician, having graduated from Bellevue Hospital Medical College in 1879. Soon after taking his degree he made his residence in Greenpoint, and joined the Kings County Medical Society. His appearance was not that of one fitted for stratagem and conspiracy; he was quiet and retiring in disposition apparently. It is generally believed that he has fallen into his distressing position on account of the lot falling to him under the arbitrary rule of some secret society with which he had become entangled.

Dr. David B. Austin, of 251 West Twenty-fifth Street, New York, is accused of causing the death of Mrs. Mary Birchley, of Brooklyn, by instrumental abortion. The accusation is based upon the death-bed statement of Mrs. B., but it is claimed by the Doctor that his operation was for the removal of polypus, and not for the purpose of producing premature labor. The case will be watched with much interest by the profession of the locality. Dr. Austin is a graduate of the College of Physicians and Surgeons, New York, Class of 1866, and has borne a good name and character among his fellow-practitioners.

CHICAGO.

(*From our Special Correspondent.*)

The Professorship of Surgery in the Buffalo Medical College has been offered, so it is reported, to Dr. Roswell Park, of Chicago. Dr. Park is a man of fine attainments, both professional and otherwise, and is at the same time a gentleman of the highest character. He has of late been devoting himself to surgery exclusively; he is one of the surgeons to Michael Reese Hospital, and Lecturer on Surgery in Rush Medical College. Buffalo will be fortunate in such an acquisition.

Rush Medical College is about to build a hospital. The plans are prepared, and the work will be pushed to completion by midwinter. The structure will be located on the north of the College building, and adjoining it, and will have an easy capacity of about fifty beds.

The building has been planned with a view to future enlargement by extensive additions. For this purpose the College has secured a lot of considerable size reaching north of the present hospital site and fronting on Congress Street. It is the design that the hospital shall eventually front on Congress Street. While the hospital is designed to be, to a certain extent, a clinical arm of the College, it is expected that it will be under the direct management of a religious order—two applications having, it is said, been already made for the care of it by such organizations. It will be to a large extent eventually a free hospital.

The District Nurse for the poor has reached Chicago. The scheme begins in a small way with one nurse at the "South Side Dispensary," and one at the "Central Dispensary." These nurses concern themselves with the needs of the out-patients of these dispensaries. They are supported by an organization under the auspices of the "Chicago Society for Ethical Culture." The nurses are to be in every case graduates of some reputable training-school for nurses.

Medical Expert Testimony in the Chicago Lard Investigation.—The facts involved in the celebrated lard investigation now in progress before the Chicago Board of Trade are, very briefly, as follows:

Mr. Peter McGeoch, a speculator in lard, bought of Messrs. Fowler Bros. 500,000 tierces of prime steam lard, that is to say, pure hog-fat. When the lard was delivered, Mr. McGeoch refused to accept it, claiming that it was adulterated with tallow and cotton-seed oil, and he sought to recover damages before the Directors of the Board of Trade.

The case is of special interest to the medical profession, since the microscope and chemistry will furnish the burden of proof in the decision of the case. The chemist of the prosecution, Mr. Delafontaine, a teacher in the Chicago High School, testified that he had discovered (1) tallow and (2) cotton-seed oil in the prime steam lard of Messrs. Fowler Bros. Mr. Delafontaine's test for (1) tallow in the presence of lard is the stearin test, and is based upon the assertion that tallow contains more stearin than lard. A portion of the suspected lard is treated with 9 to 10 volumes of sulphuric ether and absolute alcohol, equal parts; the mixture is well shaken up and allowed to stand for 24 hours, when the stearin (?) is said to crystallize out; the supernatant fluid is decanted, and the residuum washed with the alcohol and ether solution, filtered, dried, and weighed. Pure lard, according to Mr. Delafontaine, contains 1 per cent. stearin, while tallow contains a much higher percentage. Mr. Delafontaine found in the suspected specimens of lard examined from 3 to 5 per cent. stearin, and concluded that the article was adulterated with tallow.

The chemists for the defence, Profs. Remsen, Doremus, Witthaus, Sharpless, Habersham, and Haines, have abundantly demonstrated the unreliability of the stearin test. It has been found impossible to determine the average quantity of stearin in lard and tallow. Profs. Doremus and Haines, in examining different specimens of pure lard, obtained results varying as much as 800 per cent. They established the fact that Mr. Delafontaine's standard of stearin in lard was entirely too low; that lard always contains from 3 to 5 per cent., and more frequently exceeds this amount. They found that the suspected lard of Messrs. Fowler Bros. contained from 3 to 5 per cent. stearin. They demonstrated that a mixture of lard and tallow, according to the stearin test, actually contained less stearin than pure lard.

The conclusion of these eminent chemists is substantially the opinion of Prof. Allen England, one of the greatest living authorities upon commercial organic analysis, who says that it is impossible to determine by a chemical analysis whether a given fat comes from a hog or a beef.

Mr. Delafontaine testified to the presence of the second alleged adulteration—cotton-seed oil, upon the strength of the elaidin test. This test is based upon the fact that when olein is acted upon by nitrogen peroxide (N_2O_4), it is converted into a solid mass, called elaidin. Non-drying oils, of which olive oil is typical, when acted upon by nitrogen peroxide, are converted into elaidin; drying oils, of which linseed oil is typical, are affected very slightly; cotton-seed oil is affected to an intermediate degree. As Mr. Delafontaine performed the test, a portion of the suspected lard was tread with absolute alcohol (which dissolves out the olein but has no effect upon palmitin and stearin), the supernatant fluid was decanted, evaporated down, and treated with nitrogen peroxide (N_2O_4). The specimen became partially solid, and it was inferred that it contained cotton-seed oil.

The chemists for the defence proved the utter fallacy of the elaidin test, and the falsity of all inferences from such data. Two specimens, one of pure lard, the other pure lard with 10 per cent. cotton-seed oil added, were treated according to the method of the elaidin test. The mixture of lard and cotton-seed oil solidified more rapidly than the pure lard. Three specimens of the suspected lard and one specimen of pure lard solidified with the same degree of rapidity.

The absence of cotton-seed oil was absolutely demonstrated by a number of tests, of which the most important were the sulphuric acid and nitric acid color-tests of Prof. Sharpless. These color reactions do not depend upon impurities in the oil, as has been asserted, but are perfectly characteristic with bleached oils, or cotton-seed stearin.

The microscopical evidence, adduced for the prosecution by Mr. Hirsch, as to the presence of cotton-seed oil, was of a trivial character. Mr. Hirsch testified that he had discovered, by the aid of a magnifying glass, a cotton fibre in the suspected lard and asserted from this fact the presence of cotton-seed oil. Mr. Hirsch's testimony was rendered invalid by the defence upon the ground (1) that it requires a magnifying power of at least 50° to 60° to recognize with accuracy a cotton fibre, while the magnifier of Mr. Hirsch had a power of 6° to 8°; (2) that cotton fibres were floating in the atmosphere, and their presence in the lard was accidental.

Dr. W. T. Belfield, Director of the Microscopical Laboratory in Rush Medical College, was retained for the defence, at Prof. Haines' suggestion, upon the 12th of June. He furnished, by means of his microscope, the clearest and most convincing evidence for the defence. Apart from the value of his testimony in this particular case, he has made a discovery of importance in the field of microscopic investigation.

By dissolving fats in ether and allowing them to crystallize out, crystals characteristic of lard and tallow can be obtained. The crystals from an ethereal solution of lard are rhomboidal plates with bevelled ends, while those from an ethereal solution of tallow are plume-shaped, and curved in the form of the italic *f*.

Dr. Belfield dissolves 10 grains of lard in f℥ij Squibb's ether, and the solution is permitted to stand twenty-four hours, when the crystallization is complete. The crystals may be examined in alcohol or perfectly dry. The chemical composition of these crystals has not been determined, as yet, and no theory as to their nature is advanced.

Twelve lettered specimens of lard were submitted to Dr. Belfied for examination, by Dr. Tilly, who kept a careful record of the letters. The results of Dr. Belfield's examination coincided exactly with Dr. Tilly's list. Three of the specimens, pronounced by Dr. Belfield, to be free from tallow crystals, were taken from the suspected lard of Messrs. Fowler Bros.

Dr. Belfield has prepared microphotographs of the lard and tallow crystals, as well from pure as adulterated specimens, and has presented them for inspection to the Directors of the Board of Trade. He states that the characteristic crystals of tallow can be certainly discovered, when the admixture of this fat with lard amounts to five per cent. by weight; that he has reason to believe that even smaller admixtures—say two or three per cent.—can be detected with equal certainty, although he has not as yet had time to establish this latter point beyond possibility of doubt. For this is an entirely new question in science; there is no record of microscopical research upon this subject, and in the few weeks that have elapsed since this trial began, no time has been found sufficient for an exhaustive study of these crystals.

The St. Louis Medical Society and the Revision of the Code of Ethics.—It will be remembered that at the late meeting of the American Medical Association, Dr. Pollak, of St. Louis, on behalf of the St. Louis Medical Society, moved the appointment of a committee to revise the Code of Ethics, which motion was promptly laid on the table. It now appears that this resolution was not authorized by the St. Louis Medical Society, and that Dr. Pollak presented it without consulting his brother delegates. At a late meeting, the St. Louis Medical Society repudiated and condemned the action of Dr. Pollak, with only two dissenting votes.

Public Health in Connecticut.—The monthly report for May of the State Board of Health states that there has not been that marked prominence in any class of diseases that was so marked a feature of the last few months. If consumption be included, however, diseases of the lungs and respiratory system generally still hold the first rank. From all parts of the State, reports of pneumonia are made, with a greater mortality than commonly accompanies this disease, usually added to the statement of its prevalence. In many places, a great increase during May is reported, and generally bronchitis, influenza, catarrhal affections, and tonsillitis are included. Although pneumonia occurs more or less all the year through, still there has been decidedly more than usual for the season. The spring has been unfavorable to consumptives. Several cases of pleurisy and an unusual prevalence of bronchitis are also reported.

As was the case last year, the increased mortality is largely caused by climatic causes over which we have no control. The marked tendency, however, shown by diseases to take on an epidemic character should warn us in time to take every possible precaution against the introduction of cholera.

Measles has continued to prevail very extensively, and has spread from place to place, often followed by severe bronchial complications or whooping-cough, as in Monroe, where three fatal cases were due to pneumonia complicating measles. Measles is reported as very prevalent in Mystic Bridge and Thomaston, in the latter place extending more to the outlying parts of the town and the farm-houses. There has also been almost an epidemic in Winsted. The disease is also reported from South Britain, Suffield, Bloomfield, Guilford, and Hartford, in the latter place quite prevalent. Whooping-cough is quite prevalent in the southern part of the State, and generally wherever measles prevails. Scarlet fever reappeared in Hartford, and diphtheria late in the month to some degree. A case of scarlet fever was reported from Guilford, a few in Haddam, quite a number in Berlin, and of a severe type—one fatal. A case of diphtheria was also mentioned; two or three cases of each were reported from North Manchester; several of scarlet fever from South Manchester, and one fatal case of croup. Scarlet fever is also reported from Greenwich. In Mystic Bridge, Thomaston, Montville, South Britain, a mild type exists; also in Willimantic, Suffield, and Bloomfield; one fatal case is reported from the latter place. Diphtheria is not as prevalent as in previous months of the year. A few cases are reported from Hampton, Wallingford, Westport, and Bloomfield. Croup is fully as often reported as diphtheria, but not so many cases in each locality. Whooping-cough was quite prevalent in Suffield and Monroe.

Malarial diseases are becoming more prominent. The commoner forms are dumb ague and malarial fevers, together with the chronic, ill-defined forms, but occasionally a case of congestive chills is seen.

The eastern part of the State has not as yet been included in the malarial territory, although the line has been pushed to the eastward, and the disease has crept up the border towns at the southeastern end of the State, still there is no general prevalence, even where cases have occurred. Generally, where the disease has secured a footing, reports of a greater prevalence are made—that is, comparing the frequency with that of the preceding months. If last year's reports are taken as a standard, a marked falling off is seen, with exceptions, and especially in the mortality. This, apparently, reached its acme in Connecticut in 1881, for last year shows a decrease of nearly a hundred in the deaths from malarial diseases, and a considerable increase in the mortality from typhoid fever.

Military versus Civil Sanitarians.—A storm has been recently developed in sanitary circles in Bridgetown, Barbados, which has its amusing points, as showing the mistakes into which a sanitarian and even a board of health may be led when a little temper is permitted to sit at the council. It appears that a main road leading into Bridgetown passes through the garrison, and that it occurred to the senior medical officer of the latter that the establishment of a public latrine and urinals on this road would prevent the indiscriminate use of waste lands in the vicinity as depositories of the natural wastes of country people passing to and from the city. In May, 1882, he therefore made a courteous enough application to have the city authorities erect these conveniences with a view to improve the sanitary condition of the garrison and its environs. This communication found its way to the Board of Sanitary Commissioners, through the various offices of the military commander, the colonial secretary, and the governor, and here it remained pigeon-holed for several months, until the senior medical officer, having lost patience, succeeded in getting the colonial secretary to inquire into its fate. The Sanitary Commissioners replied in October that the inspector of the district had been unable to discover any nuisances, and that the Board could not see that any sanitary benefit would result from carrying out the recommendation of the senior medical officer. A conciliatory clause was added that the inspector of police had been directed to coöperate with the military authorities in suppressing nuisances in the vicinity of the garrison.

The senior medical officer immediately returned to the attack. Were it not for the responsible position he held, and the trust that had been reposed in him by his Sovereign to look after the health of her troops, he might be content to fold his hands and say, "All right," let things be; but his duty would not allow him to do this, and he must remonstrate in the most forcible, while respectful manner against the assumption of gentlemen whose experience must be very limited compared to his. As public latrines did not exist on the island, their utility could only be a matter of surmise on the part of the Commissioners, while his personal experience of them ranged from end to end of the British Empire in India. The commanding officer, from his recent service in Bombay, could, he was sure, bear him out as to the present sanitary condition of that city, due to its public latrines, although formerly it was as remarkable for its filth, as Bridgetown and its vicinity. "The stench is so great along the Hastings Road as to be sickening. How can it be otherwise? Considering the influx of thousands of people daily from the country to the town. How are the calls of nature to be attended to? Is it not plain that the people must obey these calls? and it is equally plain that those in authority must make provision for these necessities. Is the Inspector-General of Police to have the guardrooms provided with commodes, etc., to meet the demands thus made upon him," etc. He has further to add, that it is incumbent on him to forward copies of the correspondence on these subjects to the Director-General of the Army Medical Department, who may very likely consider it his province to represent to the Secretary of State for War, the inexpediency of sending white troops to this island whilst it is allowed to remain in its present insanitary condition.

The threat of having the garrison removed leads the Governor to remark: "The question is assuming rather important proportions; send the papers to the Board of Health." This was done, and in March of the present year the Board elaborated an opinion, in the form of a letter to the Governor, which extends through three issues of the *Official Gazette*—April 2, 3, and 5—to the effect that latrines erected on the roadway would be prejudicial to the public health. The Board does not pretend to have the *extensive personal experience* of the senior medical officer; but, being natives, its members have a *personal* knowledge of the place and people. It brings forward Parkes, Murchison, and others in support of its opinion; as thus, in objecting to the latrines: "Prof. Parkes lays it down distinctly that the localizing causes of yellow fever are evidently connected with the accumulation of excreta around dwellings." On the other hand, in favor of the Bridgetown method of segregated droppings, the same eminent authority is quoted: "Owing doubtless to the rapid movement of the air, there is no doubt that the excreta of man and animals, thrown on the ground and exposed to the open air, are less hurtful than sewer air, and probably in proportion to the dilution." The bad odors complained of by the senior medical officer, are by inference acknowledged, because they are defended by another quotation from Parkes: "In China, where fecal matter is so constantly applied in agriculture, the air is often filled with very pungent effluvia, yet no bad effect is produced."

But it is in respect to the odious comparison as to cleanliness between Bridgetown and Bombay, and the charge of unhealthiness against the former city that the Board of Health develops its energies. We now find the cause of the long delay in rendering the opinion. The books and reports required to furnish the necessary data were not obtainable on the Island, and had to be imported from England. On their arrival no time was lost. Tables of comparative statistics follow each other for many pages of the *Official Gazette*. The Board is not satisfied with proving that, for healthiness, the Island will compare favorably with the principal towns of the United Kingdom. It proves that, as a station for white troops, it is not surpassed in healthfulness by any station of the British army, *either in or out of the United Kingdom*.

Then feeling confident in the result of its labors, it dares the issue with the senior medical officer, by requesting that copies of the papers be sent to the Secretary of State for War, and to the Secretary of State for the colonies.

Appended by way of a *coup de grace* to the senior medical officer, is an extract from a report of the Civil Sanitary Inspector, dated April, 1882, *i. e.*, prior to the commencement of the correspondence, showing the insanitary condition of the women's latrines at the artillery barracks.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending June 30, 1883, indicate that bronchitis has considerably decreased; that typho-malarial fever, influenza, rheumatism, diarrhœa, intermittent fever, pneumonia, and measles have decreased in area of prevalence. There was no marked increase of any disease reported.

Compared with the average for the month of June in the preceding six years, measles and bronchitis were reported more prevalent; and intermittent fever, remittent fever, whooping-cough, and consumption, less prevalent during the month of June, 1883.

Including reports by regular observers and by others, dipththeria was reported present during the week ending June 30, and since, at 11 places; scarlet fever at 22 places; and measles at 17 places.

OBITUARY RECORD.—DIED suddenly in New York on July 8th, JOHN A. LIDELL, M.D., aged 60 years.

Dr. Lidell graduated from the Albany Medical College in 1848. He distinguished himself during the late war by his conscientious and indefatigable service as Inspector-General of the Medical Staff of the Army of the Potomac. At the close of the war he resigned and settled in New York. As a careful student, observer, and writer Dr. Lidell has achieved permanent reputation. His contributions to the pages of the AMERICAN JOURNAL OF THE MEDICAL SCIENCES were numerous and valuable, and the last number contains an able and thoughtful article on *Contusions of the Brain and Spinal Cord*, which is probably the last contribution to our literature from his pen.

NOTES AND QUERIES.

CORRIGENDUM.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 2 TO JULY 9, 1883.

RAYMOND, HENRY I., *First Lieutenant and Assistant Surgeon.* Granted leave of absence from July 4, 1883, to September 1, 1883, with permission to go beyond sea, and resignation accepted, to take effect September 1, 1883.—*S. O. 150, A. G. O., June* 30, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIII. SATURDAY, JULY 21, 1883. NO. 3.

ORIGINAL LECTURES.

ON INFANT FOODS.

A Lecture delivered by invitation before the College of Physicians of Philadelphia.

BY PROF. ALBERT R. LEEDS, PH.D.,
OF THE STEVENS INSTITUTE OF TECHNOLOGY, HOBOKEN, N. J.

IN attempting to discuss the problem of infant foods, I shall begin by assuming that the natural food of the human infant is the best infant food. Without pausing to give the grounds on which it is based, I shall merely add, that the conviction has constantly strengthened with the progress of chemical analyses of human milk and of the various substitutes which have been proposed, that the above assumption is the safest and least presumptuous one which can be made in the present stage of theoretic and practical knowledge.

But what is human milk? To answer this question satisfactorily, we should know at least three things: 1. All the components; 2. Their relative proportion; 3. Their chemical and physiological properties.

Strangely enough, present knowledge on all these points is very far from satisfactory. With reference to the first point, it is sufficient to state that no complete analysis of woman's milk has yet been made. As to the second, I am not referring to the fact that the milk necessarily varies with the interval since parturition, the nutrition and constitution of the mother, and numerous other variable elements, but to the much more important one, that the average composition of the milk of healthy nursing women is by no means satisfactorily established. You will be surprised, I think, on turning to the literature of this subject to find how widely different are the figures obtained by investigators, and variously adopted, usually without critical consideration, in works treating of the nutrition and diseases of children. Finally, in reference to the third point, our knowledge of the properties of the components themselves is extremely meagre. We know, as yet, very little concerning the true nature of the nitrogenous bodies, which are lumped together under the head of albuminoids. And as to the fat of human milk, no separation into the many oily and fatty bodies, of which it is made up, has as yet been attempted.

It may be said that this is foolish hypercriticism—that if we do not know everything, we know sufficient to conduct the nutrition of infants on a sound basis of adequate knowledge. But many reasons could be given under the heads previously specified for regarding the last assumption as premature. Our time will not permit us even to allude to these, but will enable us to speak only of the one practical issue which it is our business to deal with this evening. This is, granting that woman's milk is the best infants' food, in what manner should the nature and proportions of the components be determined of any substitute we may be necessitated to employ? Certainly, only by knowing, in the first place, the average composition of human milk.

As this point is fundamental, and as the wide diversities I have just alluded to existed concerning it, I have thought it well to devote the past four months to its study. In this labor I have had the cordial coöperation of Dr. A. M. Thomas, Chief of Medical Staff of the Emigrants' Asylum and Hospital, and, during the later part of the inquiry, of Dr. K. Parker, of the Infants' Asylum of New York. Both of them have given their personal attention to the collection of the samples, which, in every case, were taken from healthy women, mainly young and primiparæ. All the points of interest, with regard to the history of the women, the child, and the sample, have been tabulated and coördinated, and will probably be published in connection with a future monograph devoted to the topic of human milk. This would not be a proper place for these details, further than adding that the samples usually amounted to two ounces, were taken in most instances two hours after time of last nursing, and were generally the entire contents of the gland.

The sources of variation in the multitudinous analyses of woman's milk that have been previously published, are principally three in number—the most important being the differences in the methods of analyses; next, the variations in the constitution of the milk itself; lastly, the circumstances connected with the collection of the sample. Without delaying to discuss these matters, which would require much time and precision of statement, I shall bring before you to-night only so much of the results thus far obtained as are needed for our present purpose. They are to be regarded as an approximation, to be still further modified by incorporation of the results of other analyses still in progress.

Analyses of Forty-three Samples of Woman's Milk.

Reaction uniformly alkaline.

	Average.	Minimum.	Maximum.
Specific gravity, . .	1.0317	1.030	1.0353
Water, . . .	86.766	83.34	89.09
Total solids, . .	13.234	10.91	16.66
Total solids not fat, .	9.221	6.57	12.09
Fat, ...	4.013	2.11	6 89
Milk-sugar,. . .	6.997	5 40	7.92
Albuminoids, . .	2.058	0.85	4.86
Ash, ...	0.21	0.13	0 35

Not only was the reaction alkaline when the samples were fresh, but, with one exception, in which it was neutral, this alkalinity was found to remain twenty-four or more hours after.

The most striking feature in these analyses is the great range of variation in the amounts of certain constituents, more especially in the albuminoids, the maximum, 4.86 per cent., being nearly six times the minimum, which is only 0.85 per cent. The next most variable constituent is the fat, the maximum being more than three times the minimum. Then come the saline matters, nearly three, the last of all the milk-sugar, which differs but little from the mean (6.997 per cent.) in most samples. In other words, the most striking peculiarity in woman's milk is not the constancy, but the great variability in its composition. Furthermore, this variability is by far the greatest in the constituent most essential to nutrition, the albuminoids, and diminishes in degree of variability in proportion as the constituent becomes less and less essential to nutrition, becoming very nearly constant in the case of milk-sugar, the function of which is not nutrition but heating; by which nature appears to intend to teach us that the rate of nutrition in an infant may safely vary within wide limits, but that the animal heat of an highly organized and rapidly developing creature must be maintained *coûte qu'il coûte.* To maintain at a temperature somewhat exceeding that of an adult, a creature whose vital processes on the one hand are of great activity, while on the other hand the supplies of heat due to cerebral impulses and self-originating locomotions are extremely small, requires the rapid consumption of available fuel, and the abundance of carbohydrates in the milk supplies this most imperative want.

Without stopping to draw out the significance contained in the proportionality of the constituents, both as considered in themselves and as compared with the new-born of other mammalia, let us hasten on to the comparison of human milk with its nearest analogue. This is properly asses' milk, but as this is not and never will be generally available, it will be more profitable for us to consider the cheap and universally accessible cow's milk. For a similar reason, I shall not institute a comparison between the above average and that of the rich milk of blooded cattle, the Alderneys, Jerseys, and so on, nor with selected samples from the best ordinary milch-cows. Rather, as such comparison will be of greater practical utility, I shall adduce the analyses of unadulterated whole commercial or "market" milk. And as this market milk is itself the average of a great number of samples, it is useless, so far as it is concerned, to give the maxima and minima of its individual constituents.

As determined by methods identical with those employed in the analyses of woman's milk, I shall state, therefore, the following results, obtained upon samples of unadulterated cow's milk, such as is sold by farmers in New Jersey to the citizens of New York and Philadelphia.

Analyses of Eleven Samples of Whole Market Milk.

Water,	87.7	per cent.
Total solids,	12.3	"
Total solids not fat,	8.48	"
Fat,	3.75	"
Milk-sugar,	4.42	"
Albuminoids,	3.42	"
Ash,	0.64	"

As in the case of woman's milk, the slight discrepancies noticeable are due to the fact that the figures for "total solids" were those obtained by appropriate separate determinations, and of course do not precisely agree with the figures obtained by mere addition of the solid constituents.

Before proceeding to make a comparison, I wish to quote here the results given by König (*Chemie der mensch. Nahrungs- und Genussmittel*), deduced in each case from the analyses of many hundred samples of woman's and cow's milk, and to call attention to the fact that whilst these results include determinations effected by very many and diverse methods of all descriptions of samples, and present a distinction between caseine and albumen (a distinction which cannot be sharply effected by present analytical methods), yet as a whole they are similar to and support the inductions which I shall base upon the analyses above given.

Woman's Milk.

	Mean.	Minimum.	Maximum.
Water,	87.09	83.69	90.90
Total solids,	12.91	9.10	16.31
Fat,	3.92	1.71	7.60
Milk sugar,	6.04	4.11	7.80
Caseine,	0.63	0.18	1.90
Albumen,	1.31	0.39	2.35
Albuminoids,	1.94	0.57	4.25
Ash,	0.49	0.14	?

Cow's Milk.

	Mean.	Minimum.	Maximum.
Water,	87.41	80.32	91.50
Total solids,	12.59	8.50	19.68
Fat,	3.66	1.15	7.09
Milk-sugar,	4.92	3.20	5.67
Caseine,	3.01	1.17	7.40
Albumen,	0.75	0.21	5.04
Albuminoids,	3.76	1.38	12.44
Ash,	0.70	0.50	0.87

The same striking peculiarities are noticeable in the above analyses of woman's milk. The greatest variable is the albuminoid constituent, the maximum being more than seven times the minimum; the most nearly constant is the milk-sugar, varying little from the mean of 6.04 per cent., which is likewise the largest of the solid constituents.

When we compare woman's with cow's milk, it is the great differences and not the similarities which surprise us, and demand study, recognition, and utilization in the solution of the problem of artificial infant's food. In woman's milk we have a persistently alkaline liquid, of a somewhat animal, usually disagreeable, and very rarely sweetish taste, of somewhat greater specific gravity (1.0317) than cow's milk (1.029). Although it has less water, and greater total solids, and total solids not fat, than cow's milk, it is by no means so opaque, and with its thin and watery consistence gives us a notion the reverse of true with regard to its real composition. Agreeing with cow's milk in the fact that the milk-sugar in both is the chief solid, it differs in that its milk-sugar largely exceeds the milk-sugar of cow's milk. It likewise exceeds in fat. In albuminoids it falls far below. And whilst by present modes of analysis the separation of the so-called caseine from the so-called albumen is not accurately performed, yet the results are approximately correct, and have a very great value in pointing out the most important of all the differences between the two secretions, which is that the fraction of the total albuminoids in cow's milk which is coagulable by acids is far greater (perhaps four times) than the non-coagulable part.

In woman's milk, on the contrary, the reverse is true, and the non-coagulable part much exceeds (perhaps by more than twice) the coagulable portion. And whilst the absolute amount of ash is less, the relative amount of potash is greater, in woman's than in cow's milk.

For reasons which will appear further on, it would seem that the best solution of the problem of artificial infant feeding is to be found in the substitution of cow for human milk. But, inasmuch as the secretion of the herbivora is radically and in all particulars different from that of the omnivora, cow's milk is profoundly altered, so as to assimilate, in the ratio and nature of its constituents, human milk.

To discuss the various methods by which it has been proposed to effect this result would far outrun my present scope, which is only so much of the general discussion as relates to the influence exerted upon cow's milk by the addition of the various articles of infant food now manufactured and offered for sale. This influence, we shall find, is chiefly of a mechanical or physical character, and does not necessarily involve the discussion of those chemical changes, at present time under investigation in many quarters, the practical results of which have not yet been satisfactorily determined, and belong, therefore, to the future of this subject.

The method hitherto employed is spoken of as mechanical for reasons based partly on the practice of physicians and partly on laboratory experiments. The mere addition of water to cow's milk is sufficient to reduce the percentage of albuminoids to the same amount as its percentage in human milk. But this addition does little to diminish the size and compact character of the clot of cow's milk. This last is effected, as far as it actually is effected, which is only partially, by the addition of the various attenuants composing manufactured infant's food, whether that attenuant is starch, gum, sugar, dextrine, or other bland nutrient. This explanation of the utility of manufactured infant's foods accounts for the seeming anomalies in present medical practice, which at first sight appear very startling and inconsistent with generally accepted physiological doctrines. For whilst admitting that the secretions of the salivary and pancreatic glands are insufficient in the early stages of infancy to digest more than very limited amounts of starch, yet physicians frequently use with good results a farinaceous food like Ridge's, which contains 77.96 per cent. of starch, or like Robinson's patent barley, which contains 77.76 per cent. of starch. But when we consider that the utility of this starch is not in the way of infant's food, for which it is not adapted, but as an attenuant of the large amount of diluted milk with which it is mixed, then the seeming contradiction between theory and practice disappears.

To discover whether this interpretation is in accord with experiment, the coagulation was effected in the presence of similar attenuants. In the first place, the total albuminoids were determined in a sample of whole cow's milk, and were found to be 3.39 per cent. The so-called caseine was then separated by coagulation with acetic acid, and amounted to 2.42 per cent. On boiling the filtrate, 0.26 per cent. of albumen so called separated out, leaving a deficiency of 0.71 per cent. of albuminoids to be accounted for. A direct determination of the albuminoids in the filtrate from the albumen, gave an additional yield of 0.76 per cent., showing that both coagulation and boiling of the filtrate subsequently had left nearly one-fourth of the total albuminoids in solution.

Ten grammes of the same milk, together with 25 grammes of cane-sugar and 110 c.c. of water, were treated in like manner, the precipitates being exhaustively washed. I obtained:

As precipitated by acid, ...	3.13	per cent.
" " by boiling, ...	0.40	"
Precipitated by copper sulphate from filtrate, .	1.14	"
	4.67	"
Total albuminoids, ...	3.39	"
	1.28	"

In other words, the precipitates carried down with them 1.28 per cent. of saccharine matter, which could not be removed by washing.

Some barley-water was then made and filtered through ordinary Swedish filter paper, the clear filtrate being used in the following experiment. Ten grammes of the same milk as before were mixed with 110 c. c. of the barley-water. I obtained:

As precipitated by acid, ...	5.21	per cent.
" " by boiling, ...	0.37	"
" " by copper sulphate from filtrate, .	1.35	"
	6.93	"

That is to say, the precipitates carried down with them from the clear barley-water 3.54 per cent. of barley extract, which could not be removed by washing. In this case, the attenuants of the clot exceeded in weight the coagula themselves.

An experiment with grape-sugar yielded results closely resembling those with cane. With gelatine a very remarkable result was obtained. Ten grammes of the same milk were added to 110 c.c. of a solution of 1 part of gelatine in 150 parts of water. Although the gelatine was so attenuated, it entirely prevented the precipitation of caseine on the addition of acid, and what is likewise interesting, appeared to arrest decomposition, the white jelly not having altered after a week's standing.

Ten grammes of the same milk were added to 110 c.c. of clear starch-water (filtered through Swedish filter paper). I obtained:

As precipitated by acid, ...	3.07	per cent.
" " by boiling, ...	0.36	"
" " by copper sulphate in the filtrate,	1.08	"
	4.51	"

Or 1.12 per cent of starch carried down and not separable by exhaustive washing.

The utility of diluting cow's milk until its percentage of albuminoids does not exceed that of human milk, and adding some bland attenuant, is obvious. But the special virtues of the *extractive* of barley or oatmeal, as compared with starch, and the relative value as nutrients of sugar, gum, dextrine, gelatine, barley, oatmeal, etc., and their relative advantages when thus employed, have been very imperfectly determined. It is much to be desired that new physiological and chemical experiments directed especially to these all-important factors in infant nutrition should be instituted. I shall have occasion to refer to the same points in connection with Liebig's Foods.

An examination of the great variety of infant foods, the analyses of which are given in the following pages, shows that they can be classified most conveniently under the three heads of Farinaceous, Liebig's Foods, and Milk Foods (including condensed and preserved milk).

I. *Farinaceous.*

A.—Wheat, previously prepared by baking, including:

1. Blair's Prepared Wheat Food; 2. Hubbell's Prepared Wheat Food; 3. Imperial Granum; 4. Ridge's Food.

B.—Mixtures of various cereals:

5. "A B C" Cereal Cream; 6. "A B C" Cereal Milk; 7. Robinson's Patent Barley.

II. *Liebig's Foods.*

8. Mellin's; 9. Hawley's; 10. Horlick's; 11. Keasbey and Mattison's; 12. Savory and Moore's; 13. Baby Sup No. 1; 14. Baby Sup No. 2.

III. *Milk Foods.*

15. Nestlé's; 16. Anglo-Swiss; 17. American-Swiss; 18. Gerber's.

Class I.—A.

	1 Blair's wheat food.	2. Hubbell's wheat food.	3. Imperial granum.	4. Ridge's food.
Water, . . .	9.85	7.78	5.49	9.23
Fat, ...	1.56	0.41	1.01	0.63
Grape-sugar, . .	1.75	7.56	trace	2.40
Cane-sugar, . .	1.71	4.87	trace	2.20
Starch, . . .	64.80	67.60	78.93	77.96
Soluble carbohydrates,	13.69	14.29	3.56	5.19
Albuminoids, . .	7.16	10.13	10.51	9.24
Gum, cellulose, etc. .	2.94	undeterm'd	0.50	
Ash, ...	1.06	1.00	1.16	0.60

1. *Blair's Wheat Food.*—It is claimed that this is prepared from choice wheat in such a manner as to retain all the nutritive constituents and reject those which are irritating or otherwise objectionable. Moreover, that by cooking such physical and chemical changes have been brought about as to facilitate mas-

tication and the subsequent action of the fluids of the stomach, thereby rendering the food more easily digested. It is stated to be especially beneficial in intestinal diseases like dysentery, cholera infantum, etc.

Uncooked, this flour has a sweet pleasant taste. When cooked according to directions it forms a very smooth paste with a faint tinge of color, resembling arrowroot in its flavor and quite palatable without the addition of salt, sugar, milk, or other accompaniments.

2. *Hubbel's Wheat Flour.*—Claimed to be made from wheat alone, floured and carefully baked from eight to ten hours, at about the temperature of boiling water. "It includes all the flesh-forming constituents, earthy and saline elements of the grain, with only a portion of the starch, and of the silicated coating. It keeps without change."

This flour is quite sweet and palatable even in its uncooked form, and when moistened with the saliva is more pasty than the Blair's wheat flour. When cooked it forms a perfectly white, smooth paste, with a very delicate flavor. It is more starch-like in consistency than Blair's, a difference due in part to the larger percentage of starch, and less pronounced in flavor, this being probably due in some degree to the smaller percentage of fat. In both Blair's and Hubbel's the per cent. of gum, cellulose, etc., is extremely small, in the latter so small that it was not determined. In nitrogen Hubbel's is much richer than either of the other two preparations, and its value for purposes of nutrition correspondingly greater. The reaction of Blair's food and of Hubbell's is in each neutral.

The excess in the amount of saccharine matter in Hubbell's food above that contained in ordinary wheat flour induced me to write for particulars of the change which it had undergone. The process, I was informed, is as follows: A large baker's oven is heated to about 340° to 360° F. The flour, contained in shallow Russia iron pans, is then put in, the fire having meantime been withdrawn, the oven closed, and the flour left there about twenty-four hours. When the oven is reopened the temperature will have fallen to 100°, and after sieving, the prepared flour will be ready for use. The flour used is the best grade as made by the roller process, the second grade containing more starch, less gluten, being that bought and used by bakers.

The two following analyses, the first of Hubbell's prepared wheat flour, the second of the flour from which the first was obtained by the process of baking as conducted in the manner above described, are interesting and important as elucidating the nature of the changes thus induced.

	Wheat flour.	Same baked.
Water,	9.02	7.78
Fat,	1.01	0.41
Grape-sugar,	2.34	7.56
Cane-sugar,	2.46	4.87[1]
Starch	76.07	67.60
Soluble carbohydrates,	5.66	14.29
Albuminoids,	7.47	10.13

It will be seen that the flour has lost moisture in baking, and also a portion of its fat. These changes, however, are of little moment compared with the considerable decrease of starch and its conversion into saccharine bodies. The soluble carbohydrates are considerably more than doubled, and this change is one of the greatest value and importance, so far as the dietetic value of the prepared food is concerned. The considerable increase in the percentage of albuminoids I am unable to account for.

3. *Imperial Granum.*—It is stated to be "in composition principally the gluten derived by chemical process from very superior growths of wheat—a solid extract." Dr. Fowler states (*Amer. Journ. Obstetrics*, April, 1882), as the result of his microscopical examination, that if the material from which this preparation is derived contains any gluten at all, the "chemical process" resorted to in order to extract it has at the same time either destroyed it, or so altered its character as to render it no longer recognizable by the usual tests. This is an excellent illustration of the difficulty which is encountered in deciding with the microscope upon the constitution of a cereal after treatment, for whilst Dr. Fowler's statement of the microscopic appearance is in accordance with my own observations, yet as a matter of fact the imperial granum contains 10.51 per cent. of albuminoids. On the other hand this is not sufficient by any means to bear out the statement that the imperial granum consists principally of gluten. According to Dr. Fowler, it is simply coarse barley flour. My own observations make it a wheaten preparation.

4. *Ridge's Food*—It is advertised as "prepared from carefully selected winter wheat," reduced to an almost uniform fineness. The product is then thoroughly cooked by a steam-baking process, which gradually changes a large proportion of the starch into dextrine, excluding only the woody fibre. It is afterwards rendered a little sweet and slightly alkaline.

Dr. Fowler states (*loc. cit.*) that the Ridge's food is apparently barley flour finely ground, and that the odor, dough, and microscopic appearance indicate no other ingredients. I have placed it, in accordance with my own observations, among the wheat preparations. Both Imperial Granum and Ridge's food when cooked are very palatable. Both have a neutral reaction. Both have a considerable percentage of albuminoids, that of Imperial Granum in the two samples analyzed being the higher, and both have a very high percentage of starch.

It should be very carefully borne in mind that wheat flour after carefully baking is extensively altered, and that the albuminous bodies become considerably more soluble in water. A wheat flour, which in its original condition would yield after baking a very considerable amount of crude gluten on washing, after baking will leave a much smaller quantity, and for this reason the percentage of crude gluten in baked flours cannot be roughly estimated by washing and drying. For the same reason a baked wheat flour may be mistaken for barley flour, which gives a non-glutinous dough.

Class I.—B. *Mixture of Various Cereals.*

	6. "A B C" Cereal Milk.	7. Robinson's Patent Barley.
Moisture,	9.33	10.10
Fat,	1.01	0.97
Grape-sugar,	4.60	3.08
Cane-sugar,	15.40	0.90
Starch,	58.42	77.76
Soluble carbohydrates,	20.00	4.11
Albuminoids,	11.08	5.13
Cellulose, gum, etc.,	1.16	1.93
Ash,	......	1.93

5. "*A B C*" *Cereal Cream.*—Stated to be "prepared from the most nutritious and digestible parts of the choicest wheat and barley, with all impurities removed." It appears to be a coarse meal of wheat and barley, but I did not analyze it, the box which I purchased being probably old and its contents spoiled.

6. "*A B C*" *Cereal Milk.*—"Prepared by a scientific admixture of the nitrates and phosphates of wheat with the whole barley; and after adding the required sugar, we have secured an analysis almost identical with human milk. The wheat is first cleansed, then hulled,

---

[1] With some dextrine.

coarsely ground, and the surplus starch removed, leaving the nitrates and phosphates. The barley is hulled, crushed, and mixed with a proper proportion of the wheat nitrates and phosphates. The mixture is cooked by steam, desiccated, ground into fine flour, specks bolted out, and the requisite amount of sugar added."

The statement that this food corresponds nearly with human milk in its nutritive ingredients is untrue. The proportion between its various constituents is entirely unlike that in human milk, and more than half consists of starch, a body entirely foreign to milk.

7. *Robinson's Patent Barley.*—"Patent barley, technically, is ground pearl barley. Yet this preparation, while possessing most of the characters of what it purports to be, is somewhat unlike pure barley flour. Its dough is more adhesive, and the white color, together with the mild barley odor, suggest the admixture of wheat flour. No gluten cells are seen, but there are numerous granules unaffected by iodine, and turned red by carmine (albuminous matter). The microscopic examination shows starch granules free and in bundles, held together by the cellulose. The larger corpuscles are probably those of wheat." I have adopted this description of Dr. Fowler, although I am inclined from my own observations to regard the preparation as merely barley flour.

[1] These determinations are probably higher than they should be, owing to the influence of dextrine upon the sugar determinations, but if there is an error, it is of the same amount in every case.

The first three are dried foods, in brown or granular masses, and very sweet; the Mellin's food looking and tasting very much like pulverized candy. Their aqueous solutions besides this sweet, had an after-taste of alkaline salt. Under the microscope Horlick's food exhibited very few starch granules, some cellulose, hairs of wheat, but mostly dark bundles of entirely unrecognizable granular matters, probably converted starch. Mellin's food goes almost entirely into solution, and I failed to recognize under the microscope the minute irregular granular matter left behind. The materials sent to me by the manufacturers of Horlick's food, as representing their regular consumption, consisted of fine white wheat flour not baked, good barley malt, and pure bicarbonates of soda and potash. Singularly enough, the reaction of the Horlick food analyzed was acid; that of the Hawley's food was acid likewise, while the Mellin's food was alkaline.

The analyses reveal certain striking points in connection with these Liebig's foods. The percentage of fat is extremely low, that of grape-sugar very high. In Horlick's and Mellin's there is no unconverted starch, in Hawley's 11 per cent. In Mellin's there were 5.95 per cent. albuminoids, and, in both the others, the percentage was very low; that in Horlick's, the larger, being but 6.71 per cent. Hawley's is very light-colored, less sweet than the other two, is more finely powdered, and has a smell resembling that of a cereal which has been submitted to torrefaction. The 10.97 per cent. of starch indicates either that the wheat and barley malt have undergone very partial conversion into grape sugar, or that this percentage of starch has been added in some form after the liquid products of the conversion have been evaporated to dryness.

In my first paper upon this subject (*Sixth Annual Report of the New Jersey State Board of Health*) I fell inadvertently into an error in speaking of Mellin's food. The original table (p. 206 of that article) stated that this food contained 5.95 per cent. of albuminoids, which was correct. Subsequently a second table was prepared for convenience in writing out my work, and into this table the clerical blunder was introduced of including the albuminoids, 5.95 per cent., along with the insoluble residue, 3.46 per cent., and putting down the sum, 9.41 per cent. under the latter head, and thus leaving zero for the percentage of albuminoids. This error I am very glad to correct in this place, as well as the misapprehension into which it led me, that the supposed absence of albuminoids indicated the failure to use wheat and barley-malt in the preparation of this food. On the contrary, the constitution of the food shows that both these articles were used, together with bicarbonate of potash, and the Mellin's is a genuine Liebig's food.

In fact, the percentage of albuminoids in a Liebig's food has not the same relative significance as it has in the case of Class I., or Farinaceous Foods. This point may be best explained by an examination of the analysis of Savory & Moore's Infant Food and the Baby Sups. These are composed of the materials, out of which, by a long and tedious process of conversion, a food like Nos. 8, 9, and 10 is made. This process is as follows: Equal parts of wheat-flour and barley malt, together with a certain amount of wheat-bran added, it is said, for the sake of the adherent phosphates and nitrogenous matter, together with one per cent. of bicarbonate of potash, are mixed with sufficient water to make a thin paste. The mixture is allowed to stand at ordinary temperature for several hours, and then heated to 150°, until the conversion of the starch is completed. It is then strained, and the residue pressed and exhausted with warm water. The extract is evaporated *in vacuo*, at as low a temperature as consistent with rapidity of working, dried at a higher temperature, and, finally, by very skilful, manipulation, brought to a finely pulverulent mass, which does not contain sufficient moisture to cake together, and is a most commendable product of technical skill.

By careful selection of highly albuminous wheat and excellent barley the best results possible can be obtained. What they are, and whether or no the addition of bran increases the percentages of phosphates and other valuable constituents in the extract, I am not prepared to say. I should have very gladly complied with the wishes of manufacturers of Liebig's foods to investigate these matters for them as a matter of ordinary professional labor, but felt that my candid expressions with regard to this subject would not permit me to do so without laying myself open to the imputation of bias. But these explanations suffice to show that the percentages of albuminoids in Liebig's foods have not the same significance as in other classes of infant's foods. The starch has undergone conversion into dextrine and grape-sugar, which, being soluble, pass into the liquid extract, and are evaporated down and pass into the final product. But only that portion of the albuminous matter which is contained in particles so fine as to pass through the strainers, together with the solid albuminous matter (and this is especially valuable in the nutrition of infants), is found in the final product. This deficiency in total albuminoids therefore is inevitable, and is an evidence of the genuineness of a Liebig's food. To determine how large a proportion of these albuminoids passes into *solution* would be of great value. To this end a mode of analysis should be used for these foods, specially designed for them, and this analysis should give not only the varieties of sugar, the dextrine, and soluble and insoluble albuminoids, but the peculiar kinds of extractive. If the virtue of Liebig's foods resides only in their not containing starch, but its products of transformation, gum and dextrine, together with sufficient bicarbonate of potash to make the reaction of the infant food, like milk, always alkaline, then so tedious and expensive a process would not have to be resorted to in order to obtain a mixture which can be made directly very cheaply. If, on the other hand, the other substances extracted from the grain have an important dietetic value of their own, then the analysis should be directed to ascertain their nature and amount. This has hitherto not been done, nor do we possess the records of physiological experiments bearing expressly upon these points of inquiry. In Savory and Moore's food this process of conversion has not been effected. Neither can it be when the food is prepared according to directions. These are to put one or two tablespoonfuls of the food into a suitable vessel, mix gradually, with two or three tablespoonfuls of boiling water or milk, and cool to the temperature of new milk. The conversion of the 36.36 per cent. of starch cannot be effected so readily. If it be (and it is stated that there is no objection (!) to so doing) heated until it thickens, afterwards removed from the fire and stirred until it become fluid, then a greater amount of starch will be converted than when mixed with boiling water only, but there is no certainty nor probability that, in any case, all the starch will undergo conversion. Neither its composition nor its method of preparation explain why, when this food is prepared with water, the food is equivalent to mother's food in nourishing power, and why, as the advertisement likewise claims, when prepared with milk only, it has twice the strength. It is certainly not to the 36.36 per cent. of starch that it owes this power, nor to the 9.63 per cent. of the albuminoids of wheat and barley. In fact, this large proportion of albuminoids shows how much less of wheat and barley has actually been employed in the preparation of Savory and Moore's food, than should have been employed in order to obtain a genuine Liebig's food. For, in the latter, the fluid extract of the wheat and barley is used, and the residual matter, which is not beneficial but injurious in the nutrition of children, is strained off, so that the solid matter remaining after evaporation represents an amount of wheat and barley originally taken greatly in excess of its own weight. In Savory and Moore's food, the percentage of albuminoids is that corresponding to the sum of the weights of the ground barley malt and wheat originally taken. These are added together, along with the alkaline bicarbonate, and, when prepared for use, the insoluble albuminoids and the useless and irritating particles, which Liebig directed should be strained off, are allowed to remain in the food.

I have spoken thus severely of Savory and Moore's food, because, whilst claiming to be prepared in accordance with Liebig's principles, it actually contravenes them. The following much less ambitious preparations are worthy of more favorable comment:

Baby Sup No. 1 is advertised as an excellent substitute for mother's milk, in case of infants under four months of age. It is a very sweet, partly crushed whole oat-meal, very palatable even before cooking, and dissolving readily in the juices of the mouth. It is prepared from malted oats, and, after the conversion of the starch has gone as far as it is thought it will proceed, the oats are carefully hulled, only a residue of the coat being left in the crack of the grain. The analysis shows the lowered percentage of starch, and the increase of saccharine bodies due to this treatment.

Baby Sup No. 2 consists of wheat flour, malted barley, and bicarbonate of potash, in the proportions given in Liebig's formula. In its dry state the mixture has little taste, but becomes thin, sweet, and palatable on cooking. The analysis gives but a partial result of this change, because the food was cooked only five minutes before the analysis, whilst the directions call for a half hour's cooking. But already much of the starch has been converted into dextrine. These foods are commendable efforts to carry Liebig's views into practice, and it is to be regretted that a certain amount of care and time is required to properly cook them, and, for this reason, they will probably have only a restricted use. In Mellin's, Horlick's, and Hawley's foods this care and time have already been expended by the manufacturer, and experience has shown that few mothers or nurses can or will take so much trouble.

Keasbey and Mattison's Foods.—From the point of view above taken, it is possible to explain a peculiarity in its composition, which I failed at first to understand. This is, that the sample of this food which I examined contained no albuminoids whatever. Its advertisement states that it is an extract prepared from malted grain, dextrine, alkaline phosphates, etc., and that it is perfectly free from starch. It does not resemble the other preparations of Liebig's foods in the market, being, unlike them, a thick liquid, resembling, both in taste and appearance, some variety of molasses or syrup. My first explanation of the entire absence of albuminoids was, that no grain was used in its preparation. This is not the case. The food is not strictly a Liebig's food, but in reality a neutralized extract of malted barley. The ground malt is extracted with hot water, the liquid strained, evaporated *in vacuo*, and neutralized with bicarbonate of potash. There is no question that the albuminoids did not pass the sieve, for I could neither determine them by ordinary methods, nor get the reaction for nitrogen by the most severe tests. But, as before stated, there must be present certain extractives, and the analysis should be directed to finding them, and thus seek to explain the undoubted benefits frequently conferred by the use of this food.

Before concluding with regard to Liebig's foods, I desire to say a few words concerning the percentages of dextrine and cane-sugar reported for these foods. The former would be nearly that which would correspond to the difference between the amount of soluble carbohydrates and the sum total of grape-sugar and cane-sugar. But it is not put down in the analysis, because it was not directly determined, and I did not know how much soluble matter of other kinds, possibly soluble albuminoids and other extractive matter of great dietetic value, might possibly be thus erroneously set down as dextrine. The percentages of cane-sugar are not strictly correct, because the presence of dextrine somewhat raises the results obtained, and there is no method, so far as I am aware, of making a satisfactory determination of cane-sugar and grape-sugar and dextrine in a mixture of the three bodies. But the method applied was the same in every instance, so that, besides the cane-sugar proper which is derived from the cereal used, the added percentage due to the error arising from the presence of dextrine would be nearly the same in every sample analyzed. The investigation of this problem should also come into the complete analyses of these foods, as well as the other matters spoken of hitherto. Scheibler, indeed, has indicated a method of detecting dextrine when mingled with cane-sugar in an amount not exceeding 3 per cent.; but in these cases we have, as in Mellin's food, no less than 37 per cent. of dextrine, and 44.69 per cent. of grape-sugar as well, the cane-sugar itself being comparatively insignificant. His method is of no value for such cases.

Class III. Milk Foods.

	15. Nestlé.	16. Anglo-Swiss.	17. Gerber's.	18. Am'can-Swiss.
Water, ...	4.72	6.54	6.78	5.68
Fat, ...	1.91	2.72	2.21	6.81
Grape-sugar and milk-sugar,	6.02	23.29	6.06	5.78
Cane-sugar, . . .	32.93	21.40	30.50	36.43
Starch, ...	40.10	34.55	38.48	30.85
Soluble carbohydrates, .	44.88	46 43	44.76	45.35
Albuminoids, . . .	8.23	10.26	9.56	10.54
Ash, ...	1.59	1.20	1.21	1.21

These articles have been prepared in order to supply a food which should contain the constituents of milk to a certain extent, and yet should be free from the objections to which condensed milk is open. The attempt was first made by H. Nestlé, in Vevey, Switzerland, but at the present time many milk factories are in existence, including one in our country at Little Falls, in New York, under the management of Dr. N. Gerber. All of these milk foods consist of cereals specially prepared in combination with milk. The preparation of the Anglo-Swiss milk food is stated to be as follows: 20 parts of Russian wheat flour and 20 parts of oatmeal are made into a dough and baked. The biscuit is then ground fine, mixed with 60 per cent. of condensed milk, dried by a slow heat at 120° to 130°, ground, and sufficient wheat gluten added to bring up the percentage of albuminoids to the same amount as that present in human milk. It is evident that apart from giving a general idea of the method of manufacture, this statement cannot be regarded as correct, inasmuch as the percentage of fat in the Anglo-Swiss milk food analyzed is much less than that which would be imparted by 60 per cent. of condensed milk, The percentage of albuminoids likewise makes it doubtful whether any albuminoids in addition to those present in the milk and flour, have been added in the form of specially prepared wheat gluten.

According to Dr. N. Gerber (*Milk Analysis*, p. 70), the various milk foods in the market vary in composition as follows:

					Average.
Water, ...	5.0	to	10	per cent.	7.50
Salts, ...	1.5	"	3	"	2.25
Fat, ...	4.0	"	7	"	5.50
Albumen, . . .	9.5	to	18	per cent.	13.25
Soluble carbohydrates, .	35.0	"	55	"	45.00
Insoluble " .	15.0	"	35	"	25.00
Cellulose, . . .	0.5	"	1	"	0.75

It will be noted that Nestlé's food departs further from the average than any of the other preparations, and the American-Swiss approaches most nearly. The percentage of fat in the latter is much larger than in the other preparations, and the percentage of albuminoids is likewise the greatest. On preparing these various brands, the Nestlé, Anglo-Swiss, and Gerber's were very palatable and delicate in their flavor, more so than the American-Swiss, which had a slight rancidity connected, no doubt, with the large percentage of fat and fatty acids. Under the microscope the various milk-foods had a similar appearance, exhibiting agglomerations of starch granules and globules of milk. They all gave the starch and dextrine reaction with iodine, the reaction for dextrine being stronger in the Gerber than in the Anglo-Swiss. All had a faintly acid reaction except Nestlé's, which was slightly alkaline.

All of them have the same points in their favor—a high percentage of albuminoids, fats, and salts, this being especially true of the American-Swiss. The conversion of the starchy matters into dextrine by previous baking gives to this class of infant foods the advantages of that class of prepared cereal, which have been rendered easily assimilated by a process of previous torrefaction. The addition thereto of condensed milk has both advantages and disadvantages. The advantages are that the condensed milk is milk in a pure and safe form. Instead of being coagulated in large, cheesy masses in the child's stomach as would be liable to be the case if the condensed milk, after thinning with water, were given alone to the infant, the admixture of dextrine and torrefied flour keeps the caseine divided, and causes it to form in small flakes more nearly analogous to those forming from woman's milk. The condensed milk likewise adds a noteworthy percentage of fat, which is conspicuously absent from the other infant foods. It also adds a certain amount of milk-sugar and increases the percentage of albuminoids and valuable saline matters, more especially the phosphates. The principal disadvantage is, that condensed milk is preserved with the aid of cane-sugar, its analysis being as follows:

Water, ...	20.0	to	30.0	per cent.
Salt.	1.5	"	3.0	"
Fat.	8.8	"	12.0	"
Albuminoids, . . .	10.0	"	13.0	"
Milk-sugar, ...	10.0	"	15.0	"
Cane-sugar, . . .	30.0	"	45.0	"

Cane-sugar, therefore, being relatively by far the largest constituent, there soon arrives a point in the manufacture of milk food when the addition of condensed milk must cease. Otherwise the percentage of cane-sugar, which like other carbohydrates is very objectionable when it takes the place of a proper amount of albuminoids, would become excessive, and indigestion thereby be induced in the infant using such food. The remedy, it appears to me, would be found by using a condensed milk preserved without the aid of cane-sugar, and since this can now be successfully effected by means of Appert's method, the preparation of a milk food not open to the above objection should be soon satisfactorily accomplished. In that case we should have an infant's food with a very high percentage of albuminoids, fats, and salts; and a low percentage of carbohydrates. The sugar would be present in the form of milk-sugar derived from the milk, and as grape-sugar derived by a process of torrefaction from the meal. The last in its turn would not have to be present in larger amounts than what are requisite to supply the starch and dextrine, which are of use to prevent coagulation of the caseine in large masses.

Condensed and Preserved Milk.

	Condensed (mean of 41).	Condensed (diluted).	Preserved Alpine.	Preserved Amer.-Swiss.	Preserved Am.-Swiss (diluted).
Water, . .	30.34	88.39	58.57	59.21	87.78
Fat, . . .	12.10	2.82	13.21	11.55	3.46
Milk-sugar,	16.62	2.77	15.29	13.04	3.91
Cane-sugar,	22 26	37.1			
Albuminoids,	16.07	2.63	11.36	14.10	4.23
Ash, . . .	2.61	0.43	1.78	2.09	0.62

It will be seen that when the condensed milk is diluted until its percentage of water is about the same as in human milk, it has relatively too little fat and too little sugar (the larger portion of that also being cane-sugar) as compared with human milk. It has also too much albuminoids and ash.

Preserved milk is the result of scientific investigation applied to this subject, and its manufacture marks a great advance in the technique of the milk industry. The product, when diluted, has no cane-sugar (an abnormal constituent of milk), and the ratio of its constituents is similar to ordinary cow's milk. It differs, of course, from human milk, and requires the addition of milk-sugar, fat, and of some bland inert attenuant, like torrefied wheat or barley-flour, to overcome the general objection to any form of cow's milk as a substitute for woman's. Experiments in this direction are on foot, and will probably result in supplying a milk food not open to some of the objections urged against previous preparations of this class. The keeping qualities of the preserved milk are likewise very remarkable; its introduction is a great public boon, and cannot fail to exert a powerful influence upon the future of urban milk-supply, and the alimentation of infants.

Conclusions.—I have been frequently asked why I do not publish my own opinion as to the best of the various foods now in use. To do so would be very unwise for many reasons. But I have endeavored to do what I have regarded as of far more importance than this, which is to praise or blame just as the information afforded by physical and microscopic examinations and chemical analysis demanded, without partiality or bias, and seek out and state the principles upon which, as it appeared to me, the dietetic value of these articles of infant food depended.

To summarize the points which I have endeavored to establish:

1. Cow's is in no sense a substitute for woman's milk.

2. Attenuation with water alone is inadequate, and chemical metamorphosis, or, mechanically, the addition of some inert attenuant is required, in order to permit of the ready digestibility of cow's milk by infants.

2. The utility of manufactured infant's food is to act as such attenuants, and as such they take the place of the simple barley and oatmeal water, the sugar, cream, baked cracker, arrowroot, etc., etc., used in former times.

4. The results of both chemical and physiological analysis are opposed to any but a sparing use of preparations containing large percentages of starch.

5. It is eminently probable that besides acting as attenuants, the matters extracted in the preparation of barley and oatmeal water, and still more the soluble albuminoid extractives obtained at ordinary temperatures (whereby coagulation is prevented), by Liebig's process, have a great independent value of their own. For this reason, instead of employing starch, gum, gelatine, sugar, ect., the use of a natural cereal extractive, containing saccharine and gummy matters and soluble albuminoids as well, such as our great and inspired teacher Liebig himself advocated, is in accordance with the developments of science since his time.

6. The use of a food made up of equal parts of milk, cream, lime-water, and weak arrowroot water, as practised for years by the late Dr. J. Forsyth Meigs, and recently advocated by his son, Dr. Arthur V. Meigs, is sustained by theory, analysis, and practice. It provides for the increase of fat to an amount comparable to that contained in human milk. It adds alkali to permanent reaction, and to convert caseine into soluble albuminates. It adds a little bland attenuant. And if, in addition, the amount of milk-sugar were raised, and instead of arrowroot water, barley or oatmeal water were substituted, as the case demanded, it would approach, it appears to me, still more nearly to the conditions required.

7. The perfect solution of the present problem is to be found in the modification of cow's milk by chemical processes, so as to make it physiologically equivalent to human milk. The nature of these processes and the results to be obtained, are at present so nearly wrought out, that there is good ground for believing that such a solution of this problem is not far distant in the future.

Remarks.—All the eighteen cases presented in the above synopsis were of the type referred to in

Dr. James Tyson's paper as *malignant hæmaturia*, called in Alabama *hemorrhagic malarial fever*, and occurred in the writer's practice from 1867 to 1882, inclusive. They exclude all cases of hæmaturia, of hæmatinuria, and of melanuria not attended by the icterode discoloration and the gastric, intestinal, nervous, circulatory, and respiratory disturbances which belong to the make-up of true hemorrhagic malarial fever. In its treatment, every expedient deemed judicious to produce cutaneous action and vascular and nervous reaction and equilibration was unceasingly urged, particularly so in the early stages. Where there was a subjective sensation of great and oppressive heat, with great attendant jactitation and suspirious breathing, the assiduous wiping over of the whole surface of the body in rapid succession with thin towels wrung out of fresh cold water, or filled with pounded ice, was often attended with the very happiest effect and greatest relief. This measure never failed greatly to diminish, and often quite dispelled the yellowness of the surface. Sometimes towels wrung out of hot water were useful, and sometimes the hot and the cold were applied alternately. In the very early stages, perspiration was sometimes secured by hot air, or by bottles filled with hot water introduced under the bedclothes. Almost invariably, when the sweating became free the hemorrhage ceased, and the whole condition improved.

In nearly all the cases, to improve the condition of the digestive tract, from 1 to 4 grs. calomel, and an equal quantity of bicarb. soda, triturated thoroughly with 1 to 2 grs. of loaf sugar, were placed on the tongue to be swallowed with a tablespoonful or two of ice-water, and this was repeated every 2 to 4 hours, until about four such doses had been taken. About four hours after the last of these doses, if their action had not reached sufficiently far down the bowels to be met by enemata of hot soap-water, small quantities of solution of Epsom salts or other saline were given and repeated until the bowels were satisfactorily cleansed. This was found to be the most reliable treatment for the terrible nausea and vomiting.

Henceforth, everything that tended to disturb the stomach, or to increase its existing disturbance, was found to be the worst barrier to success, and everything that tended to quiet the stomach, or to maintain its quiescence, was the surest guide to recovery.

Here lies the point of greatest resemblance between the fever of which we are speaking and yellow fever, and the true reason, perhaps, why quinine is so dangerous and so uncertain a remedy. Some of the cases in the table which died *with quinine* might, possibly, have lived without it, for they seemed to be doing reasonably well until a dose of quinine, given with intent of aiding their condition, seemed to have the contrary effect, and to determine an unfavorable result. In Case 11, quinine had been given to the amount of 55 grains during the twenty-four hours next preceding the attack, and the quinine was continued both by the mouth and hypodermically after the seizure, until ceaseless vomiting and forming abscesses forced its abandonment. The case remained apparently hopeless many days after the quinine was stopped, and hence in the table this case is included with those in the curative treatment of which quinine is marked "not taken." In Case 13, the white boy of ten years of age had a chill (ordinary as was supposed one morning at school; went home with fever at 12 o'clock; took quinine freely during evening and early night, and before daylight took the hæmaturic chill. In this case, if the quinine did not do harm, it surely did no good.

Pellets of ice were allowed to be swallowed or to dissolve in the mouth in all cases *ad libitum;* and in three of the cases, with the view of allaying the sickness of stomach as well as to check the hemorrhage, recourse was had to sugar of lead. In one of these cases only three grains were given and the most given to either one of them was nine grains. The nausea and the hemorrhage were greatly benefited in all the three cases, but all of the three had protracted spells of lead-colic resulting. To soothe the kidneys and to guard against the suppression of their secretion, fluid extract of buchu in fʒj to fʒij doses, sometimes with and sometimes without sweet spirits of nitre, was frequently given in a little ice water. Fowler's solution is nauseating and was therefore always avoided, but a very small pill containing from one-twelfth to one-eighth grain of powdered white arsenic and a little powdered extract of liquorice was often given at intervals of four hours to six hours. I resorted to the hypodermic use of quinine in only one of these cases, and I am disposed to give the method a farther trial.

I do not think that temperament has any relation to the disease.

It will be seen from the table that:

In the 18 cases there were 13 recoveries, or 72.22+ per cent.

In the 18 cases there were 5 deaths, or 27.77+ per cent.

In the 12 cases with quinine 7 recoveries, or 58.33+ per cent.

In the 12 cases with quinine 5 deaths, or 41.66+ per cent.

In the 6 cases without quinine 6 recoveries, or 100 per cent.

In the 6 cases without quinine 0 death, or 0 per cent.

Muriated tincture of iron, whenever it could be risked on the stomach, was thought to be indicated and was freely given whenever well retained. It was a staple in the treatment of convalescents.

Below will be found a tabulated statement of six cases of hemorrhagic malarial fever seen in consultation, or by request of attending physicians, during the period from 1867 to 1882, inclusive. In these cases, as a rule, calomel was used in larger doses, and quinine and spirits of turpentine boldly and freely given. It will be seen that:

The six cases give five deaths, equal 83.344 per cent.

The six cases give one recovery, equal 16.664 per cent.

	Cases.	Approximate Age.	White.	Male.	Female	Recovered.	Died.	Quinine taken.	Primary.	Recovered with Quinine.	Died with Quinine.

RIGIDITY OF THE ANAL MUSCLES A CAUSE OF LACERATION OF THE PERINEUM IN LABOR.

BY CHARLES H. CARTER, M.D.,
OF CHICAGO, ILL.

EVERY thoughtful practitioner has, no doubt, racked his brain over the perplexing question of preventing laceration of the perineum. The question is touched or reconnoitred by every author on obstetrics, but it can hardly be said that the subject has been *handled*—its etiology and prophylaxis *fathomed*. There are still many mooted points, the discussion of which is far from being closed. There are also questions which are quite pertinent to the subject which have as yet received little or no attention, and one of these overlooked or neglected topics is the subject of this paper.

"Rigidity of the perineum" is a much-abused phrase. It is very frequently applied to a condition of defective distensibility of the perineum proper, or even to diminutive size of the vaginal outlet from a want of development of the structures which surround it. Such a perineum may, in one sense, be *rigid*, but the term should more strictly be applied only to those perinei which are anatomically normal and capable of being distended to a degree consistent with the passage of the normal child at term, but are rendered *rigid* and *undilatable* by a hyperæsthesia of the muscles which form them.

The course to be pursued by the obstetrician in each case is governed by "what's the matter." The causes of laceration or the conditions which tend to bring it about are so various and distinct that no general discussion of the subject would be satisfactory. A classification of the *causes* has, so far as I know, never been made or attempted, but the books are full of suggestions and methods as to how to prevent the lacerations, but scarcely a word can be found bearing upon the primary conditions which render these directions pertinent. The infinite variety of manœuvres recommended shows how much demand there is for light on the subject.

Having had some very embarrassing experiences with perineal ruptures in my early midwifery practice, and especially with primiparæ, I was led to review again the literature of the subject.

There is a certain percentage of cases in which a rupture may be regarded as *inevitable*, even in the hands of the most skilful attendant. The following are the most important of the conditions in which these inevitable lacerations occur: Non-distensibility from lack of proper development in the perineal structures; incompressibility or excessive growth of the child's head; the inelastic state of the vaginal and perineal tissues in females who marry late in life; the narrow pubic arch, constituting the form denominated the "male pelvis;" unnatural positions and presentations of the child; and that peculiar condition of the muscular fibres frequently met with in delicate females, rendering them unable to bear very moderate force without rupture, or that other, possibly similar anatomical condition, bordering on a fatty degeneration of the pelvic muscular tissues, found in women suffering from chronic congestions of these parts, and in those who indulge too freely in stimulating foods and drinks, and especially in the excessive use of malt liquors.

A careful study of the peculiarities of each case, however, and a judicious application of the proper measures at the proper time, may restrict the number of unavoidable lacerations to a much smaller percentage than is at present done. If reliable statistics could be had concerning the frequency of serious lacerations of the perineum, and if the suffering and danger thereby entailed could be duly appreciated, the physician would use every endeavor to honestly cheat the gynecologist by preventing, as far as possible, not only these serious injuries, but the less important ones as well, and the midwife, too often grossly ignorant, would find her services in poor demand.

In my experience, it is the truly rigid perineum that is the most likely to be extensively torn. Everything may be apparently going on well, and the perineum promise to distend easily and amply, but just at the critical moment, when the head presses hard upon the pelvic floor, the muscles contract and the whole structure suddenly gives way.

This contraction occurs more or less regularly, though not very strongly, with each labor-pain, but it reaches its climax only when the head escapes from the cavity of the pelvis and bears down upon the sensitive muscular structures guarding the outlet to the parturient canal.

Let us see what the most important of these structures are. It is evident at a glance that the small, weak muscles of the perineum proper, though they are the ones lacerated, can offer but slight contractile resistance; and moreover, they are quite elastic in the great majority of instances, so that if they were the only obstacles to overcome, the muscular fibres would readily relax, and the fibrous network protect the muscle, while it could retreat as the head advanced. But there is a powerful muscle behind and above these weaker ones which is the *causus mali*, preventing the perineum proper from retreating, and accountable for its destruction. The levator ani, the main plank in the floor, is the offender. By its attachments, its action is necessarily as an elevator not only of the anus, but of the whole pelvic floor. By the intimate interlacement of its fibres with those of the transversus perinei and sphincter vaginæ, relaxation of the latter muscles produces little if any enlargement of the vaginal opening.

That other anatomical *sine qua non*, the sphincter ani, plays also a very important *role*. Its comparatively stationary attachment being posterior, its contraction causes the perineum to recede, while it is itself drawn upward by the levator ani.

Now, in order that the perineum may most certainly avoid injury by the escaping head, it must retreat downward and somewhat forward. This it easily does when it is distensible, provided the levator ani and sphincter ani remain in an uncontracted state.

How can we prevent lacerations depending upon a rigidity of these anal muscles? Certainly not by waiting till the perineum *begins to bulge*, and then carefully regulating the amount of strain upon it. Where this method would succeed, there would be little necessity for "regulating" anything. In the majority of cases where this method is used with good results, and no preliminary measures employed, the parts would probably go through the last step of the second stage of labor unscathed, because regulating the pressure would have little effect upon the muscular contraction if that were sufficiently strong to render laceration "imminent," as such cases have been happily termed.

When the *bulging* has begun, the time for prophylactic measures in such cases is past. No amount of support to the perineal structures will counteract the pressure of the advancing head when the pains are strong. The sudden, spasmodic contraction of the anal muscles exerts a counter-pressure on the presenting part, drawing the perineum over the prominent vertex, and laceration is certain to accompany the escape of the head.

The directions for supporting the perineum, guiding the head upward, allowing head to pass during an intermission of the pain, etc., are all very excellent in their place, and should be carefully studied and practised, but their *place* is subsequent to the preparation of the parts for the emergency they are expected to meet. The various "methods" apply rather to the crisis, when it is too late for them to be of any avail in the class of cases now under consideration.

But the plan herein described, the writer is convinced, will be found efficient in the cases of rigidity of the anal muscles, except in those anomalous, precipitate labors which are occasionally so unexpected and brief as to even preclude the use of *any* preventive measures.

An attempt to solve the problem is described by Mr. Duke in the *British Medical Journal* of March 10, 1883. His method, however, though approaching the real cause of the difficulty, does not reach it, and he, like other writers on this mooted point, does not attempt to classify his cases and point out the essential indications for using his particular method. His theory of "tiring out" the perineum, and his method of accomplishing it, have probably occurred to many others, and doubtless have been put in practice, but that his plan would succeed in those cases where the muscular structures of the pelvic floor were hypersensitive, I very much doubt. His procedure is briefly as follows, and obviously only affects the perineum proper: At that period in the second stage of labor when the head has well entered the pelvic cavity, and the pains effective, during the pain he draws the perineum steadily backward with the fingers inserted into the vagina. Intermitting his traction at the cessation of each pain, he repeats the process till he exhausts the muscles, and sufficient dilatation is produced to allow the head to pass readily.

If the muscles in the anterior portion of the pelvic floor were alone at fault, no doubt the above method would overcome the difficulty, but that such cases are frequent or serious I am unwilling to admit.

The "tiring out" process must be applied to all the muscular structures obstructing the passage, and must be applied in the proper direction.

The hyperæsthetic state of the muscles may be tested, by, in a manner, simulating the action of the child's head upon them. When the labor has well advanced, and the head so far descended as to be well engaged and is making satisfactory progress, two fingers well lubricated with carbolated vaseline are hooked into the vagina, and during the pain the perineum pressed directly downward, separating the fingers as far as possible so as to distribute the pressure and act upon the posterior as well as lateral fibres of the levator ani. If there is marked "irritability" of this muscle, it will be felt to become more or less rigid as the pressure is increased, and relaxed as the pressure is withdrawn. If the test shows the presence of the hyperæsthetic state, the following procedure may be employed to "prepare" the parts for the final act: At the beginning of each pain the two fingers are introduced as before, and the perineum drawn *downward* gently at first, but gradually more strongly as the pain increases, and lessening the traction as the pain subsides. This is repeated till but little force is needed to dilate the vaginal orifice sufficiently to admit three and then all four fingers with ease. By this time the anus is patulous and the sphincter ani exhausted. Drawing the perineum backward leaves this latter muscle in its pristine tonicity; and the levator in the greater part unexhausted. Thus the sphincter is ready to draw the perineum violently backward, and the powerful action of the levator draws it upward just at the moment when the whole pelvic floor should be in a state of complete relaxation.

In cases where the muscles are excessively hyperæsthetic the thumb may be used in conjunction with the fingers, introducing it into the rectum after the sphincter has become relaxed. Mock modesty under such circumstances is reprehensible. There is nothing indelicate in this procedure when the welfare of the woman demands that nothing should be left undone which promises her security against injury. By using the thumb in this way, separate segments of the levator may be successively acted upon, and the exhaustion rendered more complete.

This "tiring out" of the anal muscles causes no apparent increase in the woman's sufferings, being done during the pains. The manipulations are carried out at the time when she is begging the physician to help her, and when the pains are strong she will hardly seem aware that he *is* "helping" her, even when he has all the fingers in the vagina and the thumb in the rectum, firmly drawing downward.

After the muscles are thus exhausted, labor should be completed as speedily as possible. If the pains are becoming weak and inefficient, the forceps may be applied at once, but if there are good pains and everything favorable for a speedy completion of the birth, the best way to keep the muscles relaxed, and also to excite the pains to still greater efficiency, is to keep the hand in the vagina, thus distending the perineum, and just before each pain begins, insinuate a finger between the head and the bony pelvis at the point where the pressure is greatest, and as the pain comes on, indent the cranial bone at that point, and slowly withdraw the finger, and permit the head to descend. Repeating this process with each pain, the head is teased along until it escapes from its osseous vise. At the same time it is guided in the proper changes of flexion and rotation, the pains are excited, and the labor hastened toward completion, and the attendant is not merely bustling about with a pretense of doing something, but is, in fact, *helping* the sufferer.

1190 MILWAUKEE AVENUE.

MEDICAL PROGRESS.

THE YELLOW-FEVER FUNGUS.—About the time that Koch first published his discovery of the bacillus-tuberculosis, CARMONA, of Mexico, published the results of his investigations as to the germ-origin of yellow fever (*Revista di Medicina y Cirugia*, Feb. and March, 1882). His paper does not seem to have excited the same interest as did that of Koch; indeed, so far as we can ascertain, it has been published in no other than the Spanish language. As to his methods of investigation and their reliability, we cannot, at present, judge, but they should at least be made known, so that competent mycologists can repeat and either confirm or refute his statements.

Carmona found certain similar bodies in the blood, urine, and vomit of yellow-fever patients. The general element, wanting in none of these substances, was a granular matter, only seen with a microscope of 1500 diameters, very abundant, ovoid, and slightly yellow, which appeared to have filaments similar to vibrating ciliæ, and having peculiar movements, with a tendency to repeat these again and again. At rare intervals, it curls itself in its greater diameter, and generally arranges itself on its side, gradually approximating the extremities until they meet; then regains its ovoid form, which is similar to that of the prostate gland. These granulations are capable of increasing or maturing, and, under special conditions, gradually lose their first movement, and then unroll themselves into *spherical* bodies of yellow color, uniform aspect and dimensions, eight or ten times larger than the first granulations. These are from 5–12 mmm. in diameter. These large granulations were those which first attracted attention in the urine of the first patients examined, and since found in the cellular tissues, serum of blisters, and other points of the organism. There were in the urine threads, evidently *mycelia*. Some are so large as to cover the whole field of view; others smaller, and, besides, there were abundant fragments of various forms and dimensions. Some were more delicate, and of a cellular aspect; others more compact and larger, of a brilliant yellow color, and of fatty aspect; some of a more reddish color; others emerald green; still others, but much more rare, of a blue color. Their diameters varied from 2–20 mmm. Cells were frequently encountered, completely empty, of rounded or pyriform shape and variable dimensions. Many of these cells were not entirely empty, but contained a red or yellow granular material, similar to the points noticed in the goldstone. Sometimes they were found conglomerated, with the same aspect as already described, moving freely, and not restrained by the enveloping cellular tissue. Finally, in the same urine were found black bodies of different forms and dimensions, more or less irregularly spherical, others ovoid, and some quite lengthened, as though a mycelial tube had become entirely carbonized.

These different elements were found in all the specimens of urine examined, both in the fatal cases, and in those which recovered. Their abundance in the urine was in direct proportion to the severity of the attack. If the specimen of urine is set away for a few days, there is no change of form in the mycelia, the empty cells, or red bodies; but the primitive granulations and the spherical yellow cells undergo the following modifications: In proportion as the urine evaporated, there was found a great quantity of granular elements, not visible when swimming in the liquid, and appearing as yellowish points of fatty aspect; in some cases appearing as the small points unrolling and being transformed into spherical yellow cells. Specimens were found in which the gradual transition from the elemental granules to the spherical yellow cells was clearly established. These, in turn, underwent different transformations: some underwent the process of gradual regeneration and separation into different fragments. (This was seen once.) In the majority of cases, the cells were gradually involved in a yellow fluid, entirely similar to that contained in the interior; but it did not appear that it transuded from these cells. As this phenomenon was repeated in a large number of cellular elements there were found, from time to time, *lakes* of this protoplasmic substance, in which the primitive cells floated. The contents of these cells are granular, and in one or two points of the circumference there appeared certain rounded elevations, which increased and unfolded into mycelial threads. These threads unfolded by preference towards the border of the object cover-glass, as though seeking the influence of the air, and, in some instances, forming an inextricable web or network with the newly formed threads, which presented an aspect analogous to that seen in certain hedges formed by rods. In the centre of the preparation, the granular elements, as well as the unfolded yellow cells, had a great tendency to collect together, forming more or less vigorous filaments. In the protoplasmic lakes there were frequently seen fat crystals, some of which appeared to be of cholesterine, others of hippuric acid, and still others of tyrosin needles grouped in spherical masses, and forming irregular crosses. These same elements were encountered in the vomited matter, having a white or greenish-yellow color, being especially abundant in large mycelial threads. In some cases, there were ovoid cells, which appeared to be due to the alcoholic fermentation described by Pasteur. In these liquids, the spherical, yellow and elementary granules suffered the same changes as already noticed in the urine. The black-vomit sediment appeared to be formed for the greater part of blackened mycelial threads, and other bodies of different forms and sizes, also black. There were also present yellow or greenish threads and elemental granules.

In one specimen of blood was found a reddish liquid, with coagula in the bottom. No blood-globules could be found; but the granules were very abundant, with very rapid movement, many of them uniting by their slender extremities, and forming small stars. The reddish bodies and mycelial threads were also found. After allowing this liquid to stand for a day or two, the following phenomena were noted: The coloring matter of the blood was arranged along the borders of the preparation, and the entire red field was furrowed in various directions by brilliant yellow threads, the color of which contrasted strongly with the red fluid.

If a portion of the urine be allowed to evaporate spontaneously, and the residue be examined microscopically, the protoplasmic substance, containing abundant spherical yellow granulations, mycelial tubes, and crystals of cholesterine and tyrosin, before mentioned, are seen. The free extremities of many of the mycelial threads were gradually dilated, somewhat resembling the extremity of the olfactory bulb. These dilated extremities Carmona calls *oögonos*, and they measured from 10–60 mmm.

If now a drop of distilled water be placed upon this residue, sufficient to bathe the cells, there will be seen an immense quantity of small, ovoid, slightly yellow granules, with their peculiar movements, and a tendency to unite, laterally, two together, by their small extremities. In a word, these granules are entirely similar to those already described as existing in all the liquids of persons having yellow fever. There is, then, a complete identity between these zoospores found in the different tissues and organisms, some being simply developed forms of others. To this fungus Carmona gives the name *peronospera lutea*, adopting Bertillon's classification of fungi.

These bodies were found in the urine, serum of vesicles, in the cellular, hepatic, and renal tissues, as endospores; in the blood as zoospores.

EXCISION OF HARD CHANCRE.—PROF. LASSAR has come (*Berliner klin. Wochen.*, No. 23) to the conclusion that excision of a hard chancre is an operation which ought to be largely practised. He argues that it can do no harm, that it replaces an unhealthy sore by a healthy, clean wound, and thus offers a chance of preventing the general infection of the system. It is generally taught, however, and we believe truly taught, that at the time of the formation of a hard sore the nearest lymphatic glands are already involved and infected. The eradication of the disease would not, therefore, be possible by the excision of the open sore; just as it would be useless to excise an epithelioma when the glands had already become affected. The question whether it would not be a wise thing to remove any continuing source of infection of the system no doubt arises; and should it be raised, the excision of a chancre is, after all, but a small affair.—*Med. Times and Gaz.*, June 23, 1883.

TUMOR AND FISTULA OF THE UMBILICUS.—DR. TILLMANNS, of Leipzig, reports in the *Deutsche Zeitschr. für Chir.*, Band xviii., the following case, which he believes to be unique, of congenital prolapse of gastric mucous membrane through the umbilical ring. The patient was a lad, aged 13, who presented just over the navel a tumor about the size of a walnut, and covered by deep red mucous membrane. This growth seemed to be attached to the umbilicus by a very thin pedicle. It was irreducible, and its size remained uninfluenced by coughing or by firm manual pressure over the abdomen. From the mucous surface of this tumor there was a secretion, very abundant on digital examination and after each meal, of a turbid and very viscid fluid having an acid reaction, and possessing the chemical and physiological characters of the secretion of the gastric glands. The epidermis of the skin around the tumor was macerated, and, as it were, digested by the action of this discharge. No visible orifice could be discovered on the surface of the tumor, and there was no history of any portion of fluid food or of fecal matter having ever been seen there. The tumor was first observed on the separation of the stump of the umbilical cord on the sixth day after birth. The midwife, in tying the cord, noticed that it was unusually thick near its fœtal attachment. The growth increased slowly in size for about nine years, and then remained stationary. Dr. Tillmanns diagnosed this condition as one of irreducible prolapse of gastric mucous membrane, connected with the stomach by a thin and no longer permeable pedicle. Chloroform having been administered to the patient, the tumor was removed by the knife. No bad symptoms followed the operation, and the lad was soon discharged. The diagnosis was confirmed by microscopical examination of the tumor, which was found to be made up of the different coats of the stomach. The central portion was composed of the serous, subserous, and muscular layers, whilst the outer covering was formed by the mucous and submucous layers. The form of an abundant glandular element indicated that this prolapse had taken place from the pyloric extremity of the stomach. This, Dr. Tillmanns states, had evidently been a case of congenital umbilical rupture containing a gastric diverticulum, a portion of which had been constricted by the ligature applied by the midwife to the umbilical cord, and had thus been cut off, leaving an exposed mucous surface. The pedicle, it is supposed, had been gradually reduced to a very thin cord by the pressure of the margins of the umbilical ring. Dr. Tillmanns has failed in finding any report of an analogous case. In all other cases that have been recorded of prolapse of mucous membrane through the umbilical ring, the protruded part had been derived either from the small intestine or from a patent urachus. This paper concludes with an interesting analysis of recorded cases of such pathological conditions of the umbilicus, as are due to persistence of the vitello-intestinal duct and of the urachus.—*London Med. Record*, June 15, 1883.

COLUTEA ARBORESCENS.—DR. CAMPARDON has recently made experiments with the *Colutea arborescens*, or European (bastard, or false) senna, with a view of determining its therapeutic properties. He used pills containing gr. jss each of extract of colutea and powdered colutea. In a second series he replaced certain purgative pills containing aloes, colocynth, and other drastics by gr. jss each of extract of colutea and extract of colutea powder, for the reason that the rejected drugs gave rise to painful gripings; some of them also producing congestion of the rectal veins, and hemorrhoids. He desired to find a pill which would act regularly and surely in cases of habitual constipation. Six subjects of habitual constipation took from one to four of the pills during the last meal of the day. In all cases the purgative effect was certain, griping being produced in a small number of cases. The pills were used in other cases, sometimes with good results, sometimes with none. In 46 cases, however, purgative effects were produced in 16 only, with a dose of one to four pills. He then used pills composed of extract of colutea and extract of rhapontic rhubarb, āā gr. jss, in some cases āā gr. ij. The patients experimented on, with three or four exceptions, had no colicky pains and always had more or less abundant evacuations. In all, 36 patients took these pills in doses of one to two. One case, however, found it necessary to take six

The pills should be taken during the last meal of the day with the first mouthful of food. Other preparations than the pills are too disagreeable to be prescribed.—*Bulletin Gén. de Thérap.*, May 30, 1883.

Melæna Neonatorum.—Dr. Epstein, of Prague, discusses this subject (*Allgem. Wien. Med. Zeit.*, No. 49, 1882), and points out that the occurrence of hemorrhage from the stomach and intestines of new-born children is by no means uncommon. He considers that a distinct disposition to hemorrhage from various organs must be recognized as belonging to the first few days of life. This disposition is made manifest or increased, when either disturbance of circulation, or disease of vessels, or of the blood itself, is present. The notable alteration in the circulation which takes place at birth must therefore be regarded as a principal cause of the hemorrhage, and especially in cases of protracted labor, or of children born in a state of partial asphyxia, or of weakly children with atelectasis of the lungs. Various conditions have been found in the gastro-intestinal mucous membrane: hyperæmia, hemorrhagic erosions, ulcerations, and actual hemorrhage. In many cases, where the mucous membrane of the stomach has been found sprinkled with small ecchymoses, small rounded ulcers have been discovered; and these have by some authors been regarded as the real cause of melæna neonatorum, the ulcers themselves being brought about by thrombosis or embolism of the gastro-duodenal vessels, secondary to thrombosis in the umbilical vein. This is probably, however, the rarest cause for the hemorrhage; the most common cause being the hyperæmia and temporary congestion of the finer capillary vessels. Although ulceration may take place with extreme rapidity after birth, it would appear that it is usually of intra-uterine origin; and several cases are recorded, where such ulceration has led to actual perforation of the intestine or stomach. Another group of cases is formed by those of children infected with septic diseases or the subjects of hereditary syphilis. In the latter cases the hemorrhage may be the only evidence of the disease, the liver being found free from any syphilitic mischief. In the cases in this group, the prognosis has been clearly shown to be unfavorable. About half of the cases end fatally, and the immediate cause of death is usually the hemorrhage itself. A few cases, however, recover with marked rapidity.

Prof. Widerhofer records an interesting case of melæna neonatorum (*Allgem. Wien. Med. Zeit.*, No. 4, 1883), in which syphilitic manifestations were very distinct, and where hemorrhages had taken place from other than mucous surfaces, the case in many respects reminding one of hæmophilia or of purpura. Such cases he regards as due to the specific affection of the blood. The prognosis is bad, and treatment by hæmostatics is of no avail.—*London Med. Record*, June 15, 1883.

Bicarbonate of Soda in Eczema.—Dr. Rousseau has successfully used a pomade of bicarbonate of soda as an external application in eczema. It seems to alter the morbid anatomical elements of the skin, and restore it to the normal state. The strength of the pomade is: Bicarbonate of soda, grs. xv; lard or other base, ℥iss. When psoriasis exists at the same time, this pomade will cause it to disappear, but it is liable to return, and is then very difficult to cure.—*Revue de Thérapeutique*, July 1, 1883.

On the Entrance of Air into Veins during Operations.—In an article on the treatment of this grave accident (*British Med. Journal*, June 30, 1883), Mr. Frederick Treves points out that it can only occur in what may be termed dry wounds. The wounded vein must be either exposed to the air, or be covered by but a slight amount of blood before it can permit of air being drawn into its interior. In a deep wound filled with blood, the accident is impossible, and the strange exemption of tracheotomy wounds from this complication may be in some way due to the free venous bleeding with which they are often associated. It appeared to him that the best precaution to adopt in cases likely to be attended with the aspiration of air into the veins was to have an attendant ready with a sponge filled with water, which could be squeezed into the wound at the first alarm. With such a measure, no time need be wasted in searching for the vein; the entrance of air would be at once arrested, and, at the most, a little clean water drawn into the circulation. This plan he adopted in two cases. Bearing in mind that the wound is most dangerous when most "dry," it will be understood that the accident has often occurred while a tumor has been torn away from its attachments, and also after a deep wound has been well sponged out.

The second step in the treatment of the accident is to endeavor to remove the air that has already entered the chest. This, he thought, could be best effected by waiting until the next expiratory movement, and then bringing forcible pressure to bear upon the front of the thorax. The air so expressed bubbles up through the water or blood that still fills the wound, and is obviously unable to reënter so long as the wound is protected in the way indicated.

The ease with which a large quantity of air was expressed from the chest in one of the cases reported would render it difficult to endorse Mr. Erichsen's statement when he says: "We cannot, by any compression that we may employ, squeeze the air out of the heart." The elasticity of the chest in the young, the superficial position of the right auricle, and the lax walls of that cavity would appear to be facts opposed to Mr. Erichsen's conclusions.

The suggestion that the air should be sucked out of the auricle through a catheter passed down one of the main veins cannot be too strongly condemned. One of the strangest proposals current is that artificial respiration should be resorted to in these cases. The reasons for this proposal are not evident. There is not only quite enough air in the thorax already, but a great deal too much, and the dyspnœa depends not upon lack of air in the lungs, but upon lack of blood. The only probable effect of artificial respiration would be the introduction of more air into the veins.

Lastly, when all the air has been expressed, the wounded vein should be seized (most conveniently with a pair of Spencer Wells' forceps), and either entirely divided or ligatured. This procedure should be adopted during the expiratory movement. By the treatment advocated, the accident may be immediately dealt with, the entrance of air may be immediately arrested, and the parts placed in a convenient condition for the expression of the air drawn in.

Eucalyptus in Whooping-cough.—Dr. Whittbauer reports four cases of pertussis, treated with tincture of eucalyptus globulus, which recovered in a little over three weeks. The dose for children from two to four years of age was five to eight drops. One of the patients, eighteen months old, suffered from well-marked rickets. After taking the eucalyptus for four weeks, not only was the whooping-cough cured, but the enlarged epiphyses were reduced, and the child, who had never before attempted to stand on its feet, learned to walk (*Memorabilien*, Nov. 15, 1882).—*Edinburgh Med. Journ.*, July, 1883.

Massage of the Uterus.—The scientific manipulations comprised under the term uterine massage may be divided into four groups: 1. Those intended to benefit lesions of which the seat is easily accessible from the exterior; 2. Those which are applied to all the lower abdominal region, and which often constitute a preliminary operation; 3. Massage of the uterus through the abdominal wall; and, 4. Bimanual massage through the vagina and abdominal wall combined. The cases of the first group are generally in superficial subperitoneal exudations, or else situated in the abdominal walls above Poupart's ligaments. Often it is necessary to apply massage to the hypogastric region; the bladder is emptied, and the patient placed on her back on a resistant surface. The operater catches up and presses between the palm and the fingers the skin and superficial tissues. The whole abdominal wall, as far up as the umbilicus, is submitted to this treatment. Then the deeper tissues are subjected to it. These pinchings should be alternated by frictions with the fingers and palms of the hand, the whole operation lasting five or ten minutes. The skin should be previously oiled, and great delicacy be used in the manipulations. In many cases the pains appear to be situated in the abdominal wall, and the massage gradually abolishes this sensibility. After this, one may, if necessary, apply massage through the vagina and abdominal wall simultaneously. When an hypertrophied uterus, for example, can be grasped between the fingers, the hands may be applied flat on the abdomen, the fingers directed toward the pubis; then, by short and steady pressure, the masseuse seeks to grasp the uterus and knead it. More often it will be necessary to apply massage through the vagina. The index and middle finger of one hand are introduced into the vagina, and their extremities, carried into the posterior cul-de-sac, push the neck forward several times, so as to give mobility to the whole uterus. The other hand is placed on the abdomen, and grasps the uterus, the fingers in the vagina serving as a fixed point. When the organ is grasped, it is steadily compressed between the fingers of the two hands for several seconds. This is alternated by lifting up the uterus. Then, the two fingers being placed in the anterior cul-de-sac, the movements already described are repeated. The uterus should be grasped, as far as possible, between the fingers, and subjected to intermittent pressure or kneading. Jackson has recommended that the fingers be also introduced into the rectum. Displacements of the uterus, flexions, and versions have been frequently treated by massage, but without signal success. Better results are obtained in chronic metritis, and especially in cases of old pelvic peritonitis. Massage is positively contra-indicated in any acute accidents or a tendency toward acute manifestations. —*Journal de Méd. de Paris*, June 30, 1883.

Iodine Painting in Smallpox.—In 1881, there was admitted to the Konotop Hospital, a woman suffering from lumbar pain and other prodromal symptoms of smallpox. To satisfy the wish of the patient, Dr. Vetroff painted the whole lumbar region with tincture of iodine. On the next day, the painted region was found covered all over with variolous rash, while the remaining surface of the body presented only two vesicles. The course of the disease was remarkably mild. Having learned this curious fact, Dr. Bojinski-Bojko (*Vratch*, No. 1, 1883), when an epidemic of smallpox broke out in his district, began to paint with iodine the anterior surfaces of the thighs in every patient who came under his notice in the prodromal stage of the disease. In all four cases treated in this way, the rash was strictly limited to the regions painted, and the course of the affection was extremely favorable. An attempt to substitute a sinapism for the iodine gave negative results.—*Practitioner*, July, 1883.

Extirpation of the Rectum, with the Formation of a Musculo-cutaneous Flap.—Prof. Busch refers (*Berliner klin. Wochensch.*, April 9) to an operation described by Hütter, in the year 1872, in which the rectum was extirpated, union between the mucous membrane and the external sphincter and integuments having been secured, so that the distressing occurrence of alvine incontinence was avoided. Only one or two instances of this operation have since been recorded, and in those cancer was the disease to be removed. It is, however, Prof. Busch remarks, in syphilitic stricture of the rectum that the operation is most eligible. This malady is one of the most painful and intractable to ordinary modes of treatment, such as dilatation by bougies or by forcible distention under chloroform, under which treatment the subsequent pain and suffering are most intense, and, when an incision is made, is not seldom attended with severe hemorrhage and fecal infiltration of the adjacent tissues, and consequent phlegmonous inflammation. Should the patient escape these dangers, he is still exposed to a recurrence of the same morbid conditions. For these reasons Prof. Busch operates in such cases, in a manner differing in several points from Hüter's description of his mode of proceeding, and relates a case in illustration.

A woman, aged 35, who had suffered from nodes on her elbows, which had, however, disappeared under the use of iodide of potassium, began to experience severe pain in defecation, the feces being evacuated in small quantities and with difficulty. Examination discovered several polypoid excrescences within the anus; the mucous membrane to the extent of three centimetres was thickened and raised into ridges forming a close, hard stricture, admitting only the end of a finger to the extent of about two and a half centimetres, beyond which healthy mucous membrane could be felt. After careful preparation of the patient, the operation was undertaken on Sept. 8, 1882. A transverse incision divided the raphé in the midst between the anus and the entrance to the vagina, and, curving on each side towards the sacrum, enclosed the anus in a semicircular incision. By division of the muscular fibres of the constrictor vaginæ and constrictor ani, the anterior surface of the rectum was reached. The septum between the anterior wall of the rectum and posterior wall of the vagina had now to be dealt with without opening into either of those cavities; the firm connective tissue could be divided only by the knife, a separation which it was difficult to effect. The posterior wall of the vagina was pressed upwards by an assistant, while Dr. Busch with his left hand pressed backwards the anterior wall of the rectum. Thus the connective tissue was put on the stretch, and the finger of the operator was made aware directly the knife came too near either wall. Moreover, the division was attended with profuse bleeding; every incision divided arteries, some of considerable size, so that altogether fifty catgut ligatures were used. The division, however, was finally effected, and above the stricture soft connective tissue could be felt around the rectum. The rectum was then divided with the scissors to the extent of half its lumen, and its edges provisionally secured to the skin by three strong silk ligatures to prevent it being drawn inwards. The division of the intestine was then completed, and the posterior surface of the stricture was reached from above. The stricture was readily detached from the loose connective tissue which filled the hollow of the sacrum, and the intestine was again divided at about the distance of two centimetres from the anus, the strictured portion, in length about five centimetres, being then shelled out. The lumen of the rectum was more than half closed by the existing sutures of the mucous membrane; the remaining portion of the external part was followed up where it was most easily accessible from the opening of the wound (incision), whilst the contact of the mucous membrane was effected in the slowest possible manner. About twenty sutures were inserted; the perineal wound was again slightly opened; the effused blood readily escaped, and some iodoform was blown in. A drainage-tube was affixed, on both sides, to the nates, and the wound closed by silk ligatures which brought the flaps into their normal position. The anus remained somewhat open, through the division of the motor nerves. The finger inserted could feel the annular form of the sutured intestine, but not any trace of constriction.

The patient was much exhausted by the length of the operation, and suffered for some hours from vomiting. The first free fecal evacuation was passed on September 12th. Some portions of feces passed behind the sutures. A few days afterwards, a feculent purulent discharge appeared at the wound, and escaped also from the vagina, in which a small perforation was discovered. The healing of the wound was retarded by diarrhœa. On January 16th, of this year, the patient's condition was satisfactory. There was a slight mucous discharge from the vagina, but not of a blennorrhagic character. The wound in the vagina, and the perineal incision, had cicatrized. The sphincter ani had perfectly recovered its power. The finger passed into the rectum could detect a slight constriction, through which the whole index finger could be passed without causing pain. The evacuation of even solid feces is easily effected.

Prof. Busch adds the mention of another case of stricture of the rectum in which he had recourse to a similar operation, which, he adds, so far as he knows, has not been employed by any surgeon previously.—*London Medical Record*, June 15, 1883.

OBTURATOR HERNIA.—Very interesting statistics on this rare affection are to be found in a pamphlet on *Hernia* by Dr. B. Schmidt, published in 1882 as part of Pitha and Billroth's well-known series. The cases where obturator hernia has been diagnosed during life are reduced to twenty-five; of these, seventeen were subjected to operation, eight were relieved by taxis, but only five altogether were saved by the two methods of treatment. Dr. Hasselwander, of Hausham, in Bavaria, records in the *Aerztliches Intelligenzblatt* a successful case of operation for strangulated obturator hernia. The patient, a country woman, aged sixty-five, had suffered for three days from colicky pains, constipation, and flatulence. On two occasions she had been seized with vomiting. Her appetite was bad, and she felt pain in the left foot. When first examined, her face showed an anxious expression, her tongue was furred, her body emaciated, and her urine was highly albuminous. The abdomen was distended with flatus. No hernia could at first be detected. There were itching sensations in the left thigh, and numbness in the entire extremity. On closer examination, the depression, plainly marked on the right side, over the adductor longus in Scarpa's triangle, was almost effaced on the left, where the same region was painful on pressure. On deep palpation, an indistinctly circumscribed hard smooth swelling was found on the inner side of the femoral vessels, over the adductor longus. On vaginal examination, fulness could be detected within the left side of the pelvis. Partial reduction was effected; but the symptoms became very serious a few days later, so that an operation at length had to be performed. The adductor longus was laid bare by an incision extending from below the pubes for three inches along the line of its outer border. That muscle was then cleared of the cellular tissue lying in its anterior aspect, and drawn inwards. The fibres of the middle part of the pectineus were divided, and a well-circumscribed swelling was in this manner exposed. The existence of hernia being now certain, the entire incision was enlarged, upon which very troublesome venous hemorrhage occurred, and it proved difficult to control throughout the remainder of the operation. The external pudic arteries were drawn aside. The swelling was about the size of a pigeon's egg, and very tense; but it fluctuated slightly on pressure. Its surface was of a purple color. Some strong adhesions were separated by the finger. By the aid of blunt instruments used with great precaution, the sac of the hernia was opened; its outer layer was aponeurotic; its inner coat consisted of a thick œdematous tissue, easily lacerated. There was no fluid in the sac, and the intestine lay immediately against its inner wall. On widening the incision in the sac by laceration till it became of a sufficient width, the intestine was found to be deeply congested and very tense. The finger was then passed into the neck of the sac, very sharply constricted by the border of the obturator foramen and the ligamentous tissue in the neighborhood of that region. Incisions were made in the inner and lower borders of the neck of the sac, by means of a straight probe-pointed bistoury. The intestine was then carefully replaced. Only the end of the little finger could be passed into the foramen. The venous hemorrhage, the depth of the incision, and the lateness of the hour at which the operation was performed, apparently without the aid of any artificial illumination, made the operation very difficult The wound was covered with an antiseptic plug. The patient passed a motion in the night, and was henceforth relieved from all intestinal troubles, though convalescence was prolonged through suppuration of the wound, the result of the damage done to the cellular tissue in Scarpa's triangle, and its extensive infiltration with venous blood. The patient, at the end of six weeks, was completely restored to health.—*British Med. Journal*, June 30, 1883.

FLOATING KIDNEYS.—DR. F. DURET has recently written a pamphlet on the diagnosis of floating kidney. The usual symptoms of floating kidney are pain in the flank, loin, or umbilical region, sometimes radiating and simulating renal or hepatic colic; or a sense of weight, sometimes even of pulsation, so that the condition is often the foundation of hysteria or hypochondriasis. Added to this, in many instances, there are digestive troubles, as flatulent dyspepsia and diarrhœa. The detection of the mobile tumor in the loin clears up many obscure cases; but Dr. Duret does not think the physical signs of resonance in the loin with a manifest depression of that region as mentioned by most writers are necessarily present. He divides the cases in which doubts have occurred as to diagnosis into three groups. In the one group, there is no appreciable tumor, but the symptoms are marked; and such cases have been mistaken for colic—renal, hepatic, and other—for neuralgia, lumbago, and even peritonitis, whilst hysteria has been a frequent diagnosis. In another group, where the signs are more evident, malignant tumors have been diagnosed. In a third, where the tumor is unmistakable, cases have been confounded with cancer of the liver, distended gall-bladder, even cancer of the stomach, splenic, uterine, and ovarian tumors—one case being actually subjected to ovariotomy. Dr. Duret's conclusions are that "renal ectopia" is comparatively rather common; its presumed rarity depending on the fact that it is so often overlooked. Therefore the possibility of its presence should be always borne in mind, and in cases of doubt no radical measures should be undertaken, on the ground that *primo non nocere*.—*Lancet*, June 30, 1883.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,
Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in registered letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, JULY 21, 1883.

INFANT FOODS.

In the paper by Prof. Leeds, which appears in this issue, we have presented some new and valuable data in regard to the chemical composition and physiological characteristics of certain infant foods. When we consider the high rate of mortality of infants, due directly or indirectly to improper alimentation, we can hardly fail to appreciate the importance of right views in regard to the composition and functions of the so-called "infant foods." This subject is, also, not without its commercial side. The preparation and sale of various kinds of aliment suited to the infant stomach has grown into a business of no small dimensions. The profits must be large if we may base an opinion on the lavish advertisement of these foods. The rivalry is keen, as any one may learn who will give even a casual inspection of the trade literature, or hear the statements of commercial travellers, or merely note the number of those employed to distribute samples of their unrivalled preparations. When the business is in active hands, and the competition close, prices fall to the lowest margin, and then, it has been said, ingenious methods of sophistication are employed to increase the profits. In a matter of such vital importance to the growth and development of the population the State should interpose, and the purity and quality of these infant foods should be made to conform to a proper standard. The work of Prof. Leeds is a timely contribution to our knowledge of the subject.

In the consideration of infant foods, the first to be taken up is human milk. This is, at the same time, the model and standard by which all other infant foods must be judged, and it is that which is most happily contrived to subserve the purposes of the growing organism. A very great variability in the composition of this fluid, in respect to its albuminoids and fat, and constancy in the quantity of its milk-sugar, are the characteristics on which Prof. Leeds places much stress. Surely he draws too sharp a distinction between the functions of the albuminoids and the carbo-hydrates. The view that the so-called heat-producing element — the sugar of milk—serves no other purpose, is now not held, since the conclusive experiments of Fick and Wislicenus, in their famous ascent of the Faulhorn. That by the oxidation of this substance force is evolved to be applied as muscular, nerve, or other force, and that it contributes to the growth and nutrition of certain tissues, are facts not now disputed.

Again, the albuminoids, although important as tissue-formers, are not so restricted in their office, but furnish force and heat to some extent. The classification of Liebig, whereby foods are arranged into tissue-forming and heat-producing, is much too restricted, and can be accepted only when thus limited.

Prof. Leeds undoubtedly expresses a fundamental truth when he says that "the problem of artificial infant feeding is to be found in the substitution of cow for human milk." The problem is solved of course when, by artificial means, the composition of the two fluids can be made to correspond. Hitherto, the devices employed to effect this have not been entirely successful. The milk of the cow, like human milk, varies greatly in the quantity of albuminoids and fats, whilst the sugar is a nearly constant quantity. Mere dilution with water serves to equalize the proportion of albuminoids; but the chief characteristic of the casein of the cow's milk —its solidity and impermeability to the gastric juice of the infant's stomach—is not readily overcome. The various artificial foods for infants serve—according to Prof. Leeds—the purpose of "attenuating" the casein clot, besides themselves contributing to nutrition. In various combinations of cow's milk food, attempts are made to be rid of this hard and indigestible casein. One of the most successful of these, in our experience, is a mixture of barley water and cream, sweetened with sugar of milk, and rendered a little alkaline by the addition of bicarbonate of sodium; and this we find is approved by Prof. Leeds from the theoretical standpoint.

The most interesting part of the lecture under consideration, and not less important than interesting, is the discussion of the various preparations intended for infant food. Our author divides them into two classes: farinaceous; Liebig's—so named because made in accordance with Liebig's original directions, but variously modified. As the lecture in its entirety is before the reader, we need not stop to comment on these individual preparations. There are, however, certain general principles, in regard to which it may be desirable to have some discussion.

It can now hardly be disputed that starch kills the infants of our day in numbers. Prof. Leeds does not, therefore, state the fact too strongly when he affirms that the results of chemical as of physiological research are alike opposed to the use of preparations containing much starch. But the law formulated after so much observation and investigation is not without exceptions. It is undeniable that now and then infants are found to grow luxuriantly on food consisting for the most part of starch. The explanation of this apparent paradox is to be found in the undeveloped state of the salivary and pancreatic secretions in the first months of life. But it appears from the interesting observations of Dr. Keating, at a late meeting of the College of Physicians, that some infants are precocious, so to speak, in the development of the glands furnishing these secretions. Whether or not this is the final explanation why many infants die on a diet of starchy food, and a few thrive on the same, remains for further investigations to determine.

We recommend to our readers a careful study of Prof. Leeds' analytical examination of the various foods now so persistently urged on the attention of the medical profession. Are they all or less than they pretend to be? Are they adapted to serve the purpose of infant foods? If they consist of the ingredients alleged, and are produced according to methods published by their originators, it is clear that they differ so much amongst themselves in composition and mode of preparation that, although intended for the same purpose, they are not equally adapted to its accomplishment. An infant food must then be selected, not because it bears the name of this or that manufacturer, but with reference to the physiological and pathological condition of the infant requiring it.

DIPHTHERIA IN GERMANY—ITS CAUSE AND TREATMENT.

An interesting discussion of this important subject has recently taken place at the Second Congress of German Physicians, sitting at Wiesbaden, April 13–16. It was participated in by Profs. Gerhardt, of Würzburg, Klebs, of Zürich, Heubner, of Leipsic, Jürgensen, of Tübingen, Rossbach, of Jena, Leube, of Erlangen, Edlefsen, of Kiel, Lictheim, of Bern, and others.

To the doctrine of the contagiousness and parasitic origin of diphtheria, there appeared to be no dissenting voice. There was rather a disposition to refine and elaborate the parasitic theory, so as to ascribe different forms of diphtheria to different varieties of fungus, such having been described by different observers in various instances, both micrococci and bacillus forms having been observed. To this view inclined the reporter, Prof. Gerhardt, and the co-reporter, Prof. Klebs. The latter referred to an epidemic he had encountered in Prague, of fulminating cases, with severe general symptoms, and especially hemorrhagic exudation into the central organs of the nervous system. In the false membrane of these cases were closely packed micrococci (spherobacteria). In another epidemic in Zürich the micro-organisms were bacilli composed of very short and narrow rods. In the latter epidemic the symptoms were very much less serious, the spleen was less enlarged, there was slight or no involvement of the kidneys, no defects of the liver and heart, and paralytic symptoms were less frequent. The children died, in fatal cases, from extension of the process into the bronchi, or inflammatory alterations in the lungs.

Edlefsen, on the other hand, claimed that in Kiel, where the bacillus form of diphtheria was more common, there was no essential difference in the course of the two forms, and that in the bacillus form, if death did not occur early in consequence of laryngeal obstruction, paralyses were frequent enough. The heart affections, in his experience, in diphtheria, did not consist always in parenchymatous degeneration, but rather in a paralysis of the nervous apparatus of the heart. This seems to us a happy suggestion of Edlefsen, accounting, as it does rationally, for those cases of sudden death in apparent convalescence from diphtheria, which have been rather loosely ascribed to heart-clot.

Gerhardt contrasted diphtheria with other infectious diseases in which, usually, the constitutional symptoms appear first, and the local manifestations later. In diphtheria, this order is reversed, although here also the fever is divisible into two periods—first that due to the local affection, which, in the lighter forms, may be the only febrile movement, to which in severe cases is added the peculiar diphtheritic fever. Gerhardt is inclined to consider as diphtheritic those slighter degrees of local involvement which we have been in the habit of regarding as follicular inflammations of such intensity as to produce circumscribed sloughs. Not only this, but Gerhardt believes we may have diphtheria without any membrane or local manifestation whatever. This, he says, is almost always of a chronic character. Klebs also speaks of chronic diphtheria, in which, after apparent recovery, intestinal symptoms appear, with enlargement of Peyer's patches, presenting the reticular appearance of the first stage of typhoid fever. Klebs also refers to a case, rapidly fatal, where the local lesion was not larger than a penny. These last are facts in connection with diphtheria which we do not recollect to have seen noted, and we especially call the attention of our readers to them.

As to therapeutics, the views advanced were quite as various as those we are in the habit of meeting at home. Thus Gerhardt discards all methods which tend to produce irritation, and thus to favor the spreading of the fungus. He observes two indications—first, the loosening of the membrane, and second, the combating of the cause of the disease. The first is favored by inhalations of steam, lime-water, lactic acid, and the action of pilocarpin. He confirms also the statement of Rossbach as to the efficiency of papayotin as a solvent or loosening remedy. The second indication is fulfilled by measures which are essentially antiseptic—viz., the use of peroxide of hydrogen, eucalyptol, iodized phenol, chloral hydrate, benzoate of sodium, hydrochloric acid, sulphite of sodium, boracic acid, corrosive sublimate, hydrofluoric acid, oil of turpentine, etc.

Gerhardt also emphasizes greatly the necessity of what he terms etiological therapeutics and rational prophylaxis—hygienic measures of a personal and general character.

Heubner holds that the local treatment of diphtheria is of comparatively little importance, and that we must combat the poison by internal remedies; Jürgensen, that care should be taken to keep the throat cleansed, but that no caustic measures should be employed. To attempt to disinfect the body would be vain, and we do better to rely upon supporting measures, and to avoid all debilitating agents.

Rossbach considers the tonsils the usual portals of entrance for the diphtheritic fungus, and he therefore, as a measure of prophylaxis, extirpates these glands if enlarged, or applies the galvano-cautery if they are small; after this, he observes no more infection. He characterized papayotin not as an anti-diphtheritic, but as a solvent for the membrane, and calls attention to an inferior preparation which in course of time loses its active properties.

Leube always applies to the throat in the beginning of the attack, and as thoroughly as possible, a mixture of equal parts of alcohol and carbolic acid. In this Gerhardt concurred, since, he says, in the beginning diphtheria is a local disease.

EXTIRPATION OF THE THYROID GLAND.

Up to 1850, there were 70 excisions of the thyroid, with a mortality of 41 per cent.; up to 1877, 146, with a mortality of 21 per cent.; up to 1883, 240, with a mortality of 11 per cent., or, in general terms, four times as many operations and one-fourth of the earlier mortality. In this country, goitre so severe as to require extirpation of the thyroid, is rare, and the comparatively large experience of the late Dr. W. W. Greene, of Portland, was for us almost phenomenal. But, as we would naturally expect, the continental and especially the Swiss surgeons, have such exceptional advantages in the study and operative treatment of these generally formidable tumors that their statistics seem equally astonishing and successful.

At the Twelfth Congress of German Surgeons, no less than four papers were presented on this subject by Kocher, of Bern, who published, some time since, in the Swiss *Correspondenzblatt*, fifty-eight cases, and now adds forty-three more, by Bardeleben of Berlin, by Wölfler of Vienna, who reported sixty-eight excisions by Billroth, and by Maas, of Würzburg.

In the evolution of the operation, two of the chief dangers—hemorrhage and septicæmia—have been, to a large extent, overcome, the latter by antiseptic treatment, and the former by a methodical ligation of all the thyroid arteries and their branches, and also of all the larger veins whose position is generally pretty well defined. The recurrent nerve must, of course, be sought and avoided. So large a proportion as seven cases in Billroth's sixty-eight suffered with tetanus, of whom two died, four recovered, and one suffered a relapse after three years. Kocher lost one-fourth of the malignant cases in his last forty-three operations, but only 5.1 per cent. in the non-malignant cases. That tracheotomy is to be avoided, even in cases of severe dyspnœa, seemed to be the general opinion, as it interfered with thorough antisepsis and the restoration of the form of the compressed and not seldom softened trachea. Kocher, when the disease is unilateral, frequently extirpates only the diseased half of the gland with good results, whereas Wölfler advocates total extirpation.

GALVANO-CAUSTY IN OPHTHALMIC SURGERY.

Battesti, in his *Thèse de Paris* for 1882, gives an account of the results obtained from galvano-caustic treatment in certain ophthalmic diseases, as carried out at de Wecker's clinic. His experience demonstrates the superiority of galvano-causty over every other method of igneous cauterization. The special advantages are, it causes but little pain, and the application is not followed by any decided reaction; the effect is limited to the point of application; it rapidly diminishes the pain of ulceration of the cornea, and it stimulates the development of the new formative materials.

The special conditions in which this practice has been utilized are as follows:

In detachment of the retina galvanic puncture gives very encouraging results. The same practice, frequently repeated, seems to be a perfect substitute for enucleation of staphylomatous eyes. It may therefore be used in simple hernia of the iris, in ciliary blepharitis, in granulations of the conjunctiva, and may supplant all cutting instruments for the most part, in the removal of tumors of the conjunctiva and eyelids.

At de Wecker's clinic, also, they have used galvano-caustic treatment with great success in pannus of the cornea, in simple ulcers, in rodent ulcers, but strangely enough, it has not been successful in serpiginous ulceration with hypopyon, in which, indeed, the method of Saemisch with antiseptic dressings, is preferable.

THE LATEST DODGE.

IN the July number of *The Manhattan* appears an article entitled "The Question of Medical Ethics." In lengthy, but most vigorous sentences, the writer, a well-known and respected physician of New York City, undertakes to make the matter plain to the general public. It does not seem to occur to him that any intelligent reader will suspect him of making an *ex-parte* statement, but with admirable composure, and most cool assumption, he goes on to place the subject "in its true light" before the very public who, as he says, "from necessity, are not and cannot be conversant with the merits of the controversy."

To such confessedly incompetent judges are the advocates of the New Code willing to appeal. Truly their cause must be in a desperate plight, when such measures are resorted to. There was a time when physicians, as members of a dignified and honored fraternity, did not think it well to parade their differences in the columns of daily papers, or in the pages of new magazines; but under the inspiriting influence of the New Code all this is to be abolished, and the laundry work of the profession is hereafter to be done in public.

We sincerely trust there will be no attempt made to meet the New-Code men upon their selected stamping ground. No good can come from pointing out to the public the gross unfairness, the ludicrous one-sidedness of such ebullitions of wrath as that which appears in the July *Manhattan*.

Did we desire to go into the merits of this article at this time we should find it no hard task to prove the charge of unfairness which must lie against it. But such is not our purpose at present, we desire simply to direct attention to the fact that one of the legitimate results of the New Code is to be the practice of appealing to the laity to judge of professional differences.

The writer in *The Manhattan* says the Code of Ethics of the American Medical Association, and of every State society excepting that of New York, tends "to make the old physician a bully, the young one a hypocrite." It certainly does not encourage such fouling of its own nest, nor prohibit its adherents from being honest men, or gentlemen.

THE MEDICAL DEPARTMENT OF SHAW UNIVERSITY.

WE have recently received the catalogue of Shaw University, at Raleigh, N. C., and a copy of the *African Expositor*, an excellent paper published in its interests.

Eighteen years ago, Rev. H. M. Tupper, its President, founded the University for the colored race. In spite of apparently insurmountable obstacles—political, personal, pecuniary, and social—his persistent courage, tact, and force of character have made it an eminent success, so that the property alone is valued at over $100,000, and last year a medical department was added to its already wide curriculum. For this the State gave ample ground, and friends have supplied the necessary funds for the erection of two large brick buildings for the new department. One contains the usual lecture-rooms, laboratories, dissecting rooms, etc., and the other is a dormitory with accommodations for sixty students. The fees for a five months' course of lectures are sixty dollars, and a graded course of three years is recommended, but two will be accepted for the present.

The principle of self-help is applied as far as possible, and many of the students have supported themselves by manual labor. Indeed, they have made a large part of the furniture and all of the bricks in the five buildings, and have sold, for the benefit of the school, over 3,000,000 more. Room-rent, lights, fuel, and board cost only eight dollars per month.

We have noticed this institution at some length, because we believe it is doing wonderfully good work for the colored people of this country. They need physicians of their own race, and this medical school will not only provide them, but will also open a new avenue of self-support to the black man. The whole number of students in the University is 347, of whom 11 are medical students.

IT seems that in New York a certain valued citizen, named Okenberg, was at the point of death, and the doctor, evidently a man of a sanguinary mood, declared that to save his life transfusion was the only remedy. A negro named Banks thereupon offered him q. s., and, most fortunately, in spite, too, of this shocking mechanical miscegenation, Okenberg got well. He alleges that he paid Banks privately, and also paid again for his services in the hotel bill. But Banks—his name is evidently and appropriately financial in its origin, and not riparian—was not thus to be put off. He is now suing the patient for $250 as an equivalent,—$192 for eight ounces of blood of 240 drops to the ounce, at ten cents a drop, the remainder being for his services.

It is a nice question this, the price per drop. If poor Banks' blood be worth ten cents, how much would Vanderbilt's or Jay Gould's be worth?

SOCIETY PROCEEDINGS.

THE PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday Evening, May 24, 1883.

THE PRESIDENT, JAMES TYSON, M.D., IN THE CHAIR.

CARCINOMA OF THE COLON AND STOMACH, WITH CARDIAC LESIONS.

DR. J. T. ESKRIDGE presented the specimens, with the following history:

Peter L., aged 60 years, Irishman, by occupation a dyer, was said to have enjoyed fair health until two years ago, when he suffered from a severe attack of inflammatory rheumatism. He knew but little of his family history, and could not give the cause of his parents' death. He never complained of heart disease. During the latter part of the year 1881, about eighteen months before his death, he first began to complain of pain in the epigastric region, attended by eructations of a sour, slimy liquid. Soon he experienced a sense of nausea coming on an hour or more after eating. About three months after the first appearance of symptoms of gastric disease, he began to vomit. At first vomiting occurred occasionally, but soon it took place several times a week, and finally once or twice each day. He lost flesh rapidly.

In the early part of March, 1883, he was admitted into the wards of the St. Mary's Hospital, when he came under my observation for the first time. He was very weak and greatly emaciated. His pulse—of the Corrigan type—was 80 per minute. When resting in the recumbent posture his breathing was quiet. Temperature was usually one degree below normal. The radial and temporal arteries were rather hard, and the latter were tortuous. A diastolic murmur and a systolic murmur were heard at the aortic orifice. The impulse of the heart was not very strong, and the left ventricle did not appear to be greatly enlarged. The lungs were emphysematous, and an area of impaired resonance, amounting to almost dulness, was discovered on each side of the spinal column, opposite the spines of the scapula. An indurated mass, apparently about the size of a walnut, more or less movable, was felt in the epigastric region to the right of the median line, and about midway between the ribs and the umbilicus. The growth was not sensitive to rather rough manipulation, and he had not experienced any pain for a number of months. His bowels were sluggish, and it required active agents to evacuate them. No tumor beside the one connected with the stomach was felt or suspected in any other portion of the abdomen. He vomited almost daily. The liver and spleen were not enlarged. The urine was free from albumen.

By securing daily evacuations from the bowels, and giving him nutritious, easily assimilated food, the vomiting nearly ceased. He improved, and left the hospital the latter part of March. Early in April, he was admitted to the Jefferson Medical College Hospital, where he came under my care the first of May. At that time he was eating but little, the abdomen was considerably distended by gas, and his bowels required repeated large enemata, or enormous doses of purgatives to secure their action. On the fourth of the present month, he experienced great pain in the right iliac region and just to the right of the median line of the abdomen, midway between the pubes and umbilicus. Over and around the latter painful spot—a circumscribed, highly tympanitic and sensitive area, about the size of a man's fist, was observed. Circumscribed peritonitis was diagnosed. Large doses of morphia, administered hypodermically, were required to relieve pain. The stomach became irritable, and the peritonitis more general. He died during the afternoon of the eighth of May.

Sectio cadaveris four hours after death, by the pathologist of the hospital, Dr. Morris Longstreth.

Thorax.—About seven ounces of perfectly clear serum was found in the pericardium. No evidence of pericarditis existed. Left side of heart firmly contracted; right side relaxed and contained considerable fluid blood. Right side of heart and its valves normal; no lesion found at mitral orifice. Free borders of the leaflets of the aortic valve are thickened and slightly contracted, allowing regurgitation to take place at the aortic orifice. Aorta atheromatous, dilated, and decidedly roughened near the aortic orifice. Left ventricle slightly hypertrophied.

Lungs deeply pigmented, and generally emphysematous; both congested posteriorily; surfaces of both apices covered with patches of fibroid thickening. Abundant evidence of diffuse peri-bronchitis chronica was present. Bronchial tubes of the lower lobes of both lungs much dilated. Bronchial glands at the root of the lungs very much enlarged.

Abdomen.—On opening the abdominal cavity, considerable very offensive gas escaped from the upper part. On the right of the median line of the abdomen, from the umbilicus downward, the abdominal wall anteriorly was adherent to omentum and intestine over an area of about five inches in diameter. Lower third of abdominal cavity was filled with a yellowish-white cloudy liquid. Intestines bound together by numerous adhesions. The stomach, which I show you, is small, and its coats are thickened. The hypertrophy of the wall of the stomach is slight at the cardiac end, but gradually increasing, becomes considerable at pyloric. The wall of the pylorus and adjacent portions of the stomach and small bowel is about one-half inch thick. At this point the mucous surface presents several fungous-looking outgrowths. The small bowel, with the exception of about half an inch of the upper portion of the duodenum, appears normal. In the colon, about six inches from the ileo-cæcal valve, is a stenosis, barely admitting the end of my little finger. The wall of the colon at the point of narrowing, which extends three or four inches of the length of the bowel, is greatly hypertrophied, measuring about one-third of an inch in thickness. The colon, from its beginning to point of constriction, is dilated into a large pouch measuring four and one-half inches in diameter. The dilated portion of the bowel presented a dark gangrenous appearance, distended by gas, was adherent to the anterior wall of the abdomen, just to the right of the median line. The remaining portion of the large bowel appeared to be healthy. No enlargement of the mesenteric glands was observed. Liver, spleen, and pancreas were small and firm, but free from malignant growths. Both kidneys were reduced in size, contained a few small cysts, their cortical substance was lessened, and their capsules were abnormally adherent in places.

Remarks.—It is worthy of remark that although considerable thickening and induration existed at the pyloric end of the stomach, the orifice remained sufficiently patulous to allow the food to come in contact with the intestinal juices. Another point of interest is seen in the existence of so great amount of narrowing in the calibre of the large bowel with no symptoms, except easily obviated constipation, until a short time before the man's death. It seems to me remarkable that a bowel so dilated above the point of a narrow constriction should be able to respond painlessly to purgatives.

MITRAL STENOSIS AND REGURGITATION FOLLOWED BY TRICUSPID REGURGITATION AND GENERAL DROPSY.

Dr. J. T. Eskridge presented the specimens, with the following history.

Ellen D., 48 years old, single, servant, was born in Ireland. Her mother died from some chest trouble when about forty years of age. Her mother's relatives were subject to "pleurisies and rheumatism." Her father lived to an advanced age. Ellen enjoyed good health until six years ago, when she suffered from three attacks of rheumatism within a few months. During each attack she was lame in the feet and legs. After those rheumatic seizures, she was comparatively comfortable until the early part of the year 1879, when she noticed that going up and down stairs, or prolonged or active exercise, exhausted her more than usually, and gave rise to palpitation of the heart. In the year 1880, she had another slight attack of rheumatism. She said her feet were almost constantly swollen during the years 1881 and 1882. Last summer her general health improved, but when the cold weather of the following fall and winter set in, increasing dropsy and dyspnœa returned. She was admitted into the wards of the St. Mary's Hospital, December 5, 1882, suffering greatly from general cardiaç dropsy and associate symptoms. One month later it was noted, that she temporarily improved after her admission, but the dropsy recurred and she failed rapidly.

January 10, 1883, her condition was observed to be as follows: She was jaundiced, irritable, and morose. She dozed frequently, her mind seemed clouded, but she was very restless. The tongue was heavily coated, breath had an offensive urinous odor, stomach was irritable, and anorexia almost complete. The urine was diminished in quantity, and contained abundance of albumen. Effusion existed in each pleural cavity, slight in the right, but the left side was filled up to the lower angle of the scapula. The pericardium contained an increased quantity of liquid. The lungs were congested, and numerous moist bronchial râles were present. Arterial pulsation was seen only in the carotids. Visible venous pulsations were very pronounced in the veins of the neck, and in one or two superficial veins on the anterior surface of the chest. After emptying the veins and exerting pressure upon them, they were observed to fill from the cardiac side and again pulsate while the finger was still firmly held against the vessels. A wavy impulse extending over a large area was seen. The cardiac pulsation was most marked just below the lower end of the sternum.

The pulse was very irregular and difficult to count, being about 120 per minute; it was intermittent, and irregular in volume and frequency. The variations of the pulse were most prominent when the hands were raised above the head. The impulse of the heart was felt over a large portion of the anterior surface of the chest. The area of the cardiac pulsation was bounded on the left by a point in the fourth intercostal space external to the left nipple; on the right by a point one inch internal to the right nipple; below by a point two inches below the sternal notch, and above by the left second intercostal space. Hepatic venous pulsation was very distinct. Percussion dulness was increased most on the right side. The pulmonary and aortic valves were apparently free from disease. A presystolic murmur, whose seat of intensity was over the left fifth costal cartilage, was heard over the anterior surface of the chest from nipple to nipple, and in the left axilla. It was difficult to determine whether the murmur was audible posteriorly, as the bronchial and crepitant râles and rapid breathing were confusing. Four or five days later, the presystolic murmur ceased to be audible. At that time general anasarca was well pronounced. January 24, she went into a semi-conscious condition, which gradually deepened into coma. She died January 26. She expectorated considerable blood and frothy mucous during the last month of her illness.

Sectio cadaveris twenty-four hours after death. Body well frozen. Considerable adipose tissue still remained. Thoracic and abdominal cavities only examined.

Thorax.—Left pleural cavity almost completely filled with a thin, straw-colored, serous fluid. Right pleural sac nearly half full of a similar effusion. There were no pleural adhesions. The left lung was crowded into a small space and congested; the lower lobe sank in water. The right lung was being encroached upon by the effusion, and its lower lobe was consolidated; the upper emphysematous.

The pericardium contained about six ounces of fluid similar to that found in the pleural cavities. No adhesions or patches of fibrinous exudation were seen on the surface of the heart. The cavities of the heart were relaxed and filled with dark fluid blood. The right auricle is greatly dilated. The tricuspid orifice admits the ends of the thumb and all the fingers of one hand up to the distal joint. The right ventricle is dilated and its wall is thickened. The tricuspid valve is insufficient. The valves at the pulmonary and aortic orifices are thin but competent; these orifices are not constricted. The wall of the left ventricle seemed to be thickened, and the ventricle is slightly dilated. The left auricle is greatly dilated. The curtains of the mitral valve are adherent to each other near their attached borders, and constrict the orifice, which they are no longer able to close, into a round opening only large enough to admit the end of the index finger.

Abdominal Cavity.—The bloodvessels of the stomach and bowels distended. The mucous membrane softened. Liver, heavy, dark, and grated under the knife. Spleen, enlarged, congested, and denser than normal. Pancreas, healthy. Both kidneys were congested, slightly cirrhotic, but contained considerable functionating tissue. General dropsy is rare in cases of mitral stenosis, except, as in the present instance, where it is combined with mitral insufficiency. No thrill was present during my attendance, which extended over a period of four weeks immediately preceding her death. The mitral presystolic murmur ceased to be audible during the last two weeks of her life. The absence of the presystolic murmur in cases of extreme stenosis of the mitral orifice, late in the disease, when the heart is weak and is acting rapidly and irregularly, has led some observers to believe that the murmur is frequently absent throughout the course of this form of valvular lesion. To this point I directed special attention in a recent paper on the "Diagnosis, Prognosis, and

Treatment of Mitral Stenosis," read at the last meeting of the Pennsylvania State Medical Society.

CONGENITAL MALFORMATION OF THE HEART WITH CYANOSIS; DEATH AT THE AGE OF TWENTY-NINE YEARS, FROM PULMONARY TUBERCULOSIS.

Dr. J. T. Eskridge gave a detailed account of the above case. The patient, a man, twenty-nine years old, had never been strong and able to run and play like other boys without suffering from severe palpitation of the heart. So far as the man could remember, he did not become blue before his twelfth year. After the occurrence of cyanosis his breath became much worse. He had rarely experienced pain in the region of the heart. One year ago, he first observed pains shooting through the upper portion of the right side of the chest. These continued and at times were severe, being sharp and lancinating in character. From the first appearance of the pains he began to lose flesh and strength. About the time of the beginning of the chest pains, a dry, hacking cough commenced, but expectoration was not profuse until a few weeks before he first saw him, when he took a heavy cold, which was followed by high fever, great prostration, and profuse night-sweats. He was admitted to the St. Mary's Hospital, January 2, 1883. The surface of his body presented a dusky hue, and his face, neck, hands, and feet (especially the fingers and toes) were quite blue. When he sat up, the blue color of the mucous surface of lips deepened into dark purple. The distal phalanges of the fingers and toes were hypertrophied, and the small superficial veins of the face, fingers, and various other portions of the body were easily seen and counted. The upper lobe of the right lung was consolidated and contained a cavity; the lower lobes were partially infiltrated. In the left lung the lower lobe was solid, and the upper was being infiltrated. Over the left lung, pleuritic friction râles were numerous. No venous pulsation was discovered. A presystolic thrill was felt in the third and fourth intercostal spaces to the left of the sternum, and was barely appreciable in the third intercostal space at the right border of the sternum. Percussion dulness was increased laterally. The cardiac impulse was felt and seen in the fourth intercostal space external to the left nipple.

A systolic and a presystolic murmur with their seats of intensity near the left fourth costo-sternal articulation were heard. The systolic murmur was audible anteriorly over a large area, and posteriorly at the lower angle of the left scapula. Anteriorly the systolic murmur was heard as low as the seventh rib on each side the sternum, faintly just below the left clavicle, but it was lost just below the right clavicle. The systolic murmur was audible in the left axillary region, but not in the right. The presystolic murmur was limited to a small area. The next three days the temperature varied from 100° to 102.5°. On the 6th, he coughed up several mouthfuls of blood unmixed with mucus. From the 7th to 11th, there was profuse expectoration of purulent matter containing small quantities of blood. Breath was very offensive, and the apex of the right lung was breaking down rapidly. Diarrhœa was rebellious and exhausting. He died suddenly on the morning of the 12th.

Post-mortem examination was made about four hours after death. The lungs were infiltrated by tubercle. The left pleural cavity had been obliterated by general pleuritic adhesion, the right contained about three pints of sero-sanguinolent fluid.

Heart.—Numerous pleuro-pericardial adhesions were present. The pericardium was not inflamed on its internal surface, and was nowhere adherent to the heart, but it contained about two ounces of a straw-colored, serous fluid. The heart was anæmic, flabby, and dilated. Its cavities contained a small quantity of fluid blood. No heart clot had formed. The right auricle, including its appendix, was enormously dilated. The right auricular wall was somewhat thickened. Across this auricle a thin, membranous strip stretches from right to left and from above downward. Its attachment above was at the upper portion of the auricle to the right of the appendix, below at the left margin of the tricuspid orifice. The imperfect septum, he thought, had been an attempt by nature to divide the auricle into two nearly equal compartments. The inter-auricular septum was imperfect, the foramen ovale being sufficiently patulous to admit the passage of his thumb from the right auricle into the left. The right auriculo-ventricular orifice was enlarged and admitted the ends of the thumb and all the fingers of one hand. The right ventricle was dilated to nearly twice its normal size. Its wall was not much thickened. A patch of fibroid induration, one inch long by half an inch wide, was seen on its endocardial surface. The anterior and posterior segments of the tricuspid valve were united and formed one large leaflet. The left segment was so situated that it could not have aided materially in closing the auriculo-ventricular orifice. The greater portion of the imperfect segment was stretched across the ventricle near the apex of the heart, and more or less obstructed the current of blood from the ventricle into the pulmonary artery. Free regurgitation at the tricuspid orifice was permitted on account of the large size of the orifice and the imperfect condition of the valve. The other valves of the heart were thin but competent. None of the orifices of the heart were constricted. The left cavities of the heart were rather small. The pulmonary artery was smaller than normal.

No special disease besides a fatty condition of the liver was seen in the abdominal organs.

In his remarks on the case, Dr. Eskridge said that the membranous strip which extended across the right auricle vibrated with the auricular current of blood, and probably had given rise to a presystolic murmur. If the blood in struggling through the patulous foramen ovale had given rise to a murmur, it also would have been presystolic in time. He stated that the presystolic murmur in the case was well defined and easily distinguished from the systolic one, and thought it was unfortunate for the science of physical diagnosis that both these conditions existed in the same heart. He knew no means by which one would be able to attribute the presystolic murmur to one or both of them, since it was not positive whether an inter-auricular current was capable of developing a presystolic murmur. He desired that the heart should be referred to a committee of three for a fuller report on the congenital malformation.

Dr. Nancrede referred to the development of the heart as explaining such variations, etc. It was referred to a special committee for examination.

Dr. J. T. Eskridge presented the specimens from a

CASE OF EXTREME MITRAL STENOSIS, DEATH RESULTING IN A FEW MONTHS FROM SEQUENTIAL LESIONS WITHOUT GENERAL DROPSY,

with the following history. Charlie, æt. fifteen years, died in St. Mary's Hospital during the latter part of December, 1882. In February of that year, during my term of service, he first came to the hospital, suffering from acute bronchitis. The attack ran its course in a week or two, but the heart, during and after the seizure was exceedingly irritable, frequently beating from 120 to 150 times per minute. Infrequently he complained of pain over the præcordial region. The heart was repeatedly and carefully examined, but no endocardial murmur or pericardial friction-sound was heard. No thrill or friction fremitus was felt. He was kept in the recumbent posture, and counter-irritants were applied to the præcordium. At the end of about two weeks, he left the hospital feeling tolerably well, although the cardiac pulsations were rarely below 100 per minute, and a little exercise or excitement of any kind, would increase them to 120 or more.

In August, 1882, he reëntered the hospital, and was again suffering from acute bronchitis, with free secretion attended by numerous subcrepitant and large moist bronchial râles. After the subsidence of that attack, which took place in about a week, a decidedly rough and rather long presystolic murmur was heard. During the remainder of his life he stayed in the hospital, and was engaged most of the time in waiting upon the sick in the ward. Ascending and descending stairs, and active exercise of any kind, greatly exhausted him, causing the heart to beat tumultuously, and he to pant for breath. He rapidly grew worse, and by the latter part of November, he was spitting quantities of blood rather frequently. The lungs soon became so engorged that the frequent hæmoptysis did not relieve them. During most of December, he remained in bed propped up by pillows. The last two weeks of his life, he was air-hungry, and gasped for breath. His extremities were cool and cyanosed, his face was of a dusky hue, and he expectorated large quantities of blood and frothy mucus. No general dropsy existed. Considerable albumen was found in the urine. Physical signs of pulmonary congestion and œdema, bronchitis, pleurisy with effusion, pleuro-pericarditis, and pericarditis with effusion in the pericardium, were present during the last few weeks of his life.

Sectio Cadaveris.—Numerous recent and old pleuritic adhesions were found, especially in the neighborhood of the heart. Pleuræ were slightly adherent to the upper portion of the pericardium by means of recent exudation. Considerable fluid, containing only a trace of lymph, and no pus, was seen in the pleural sacs. The pericardium contained several ounces of nearly clear serum. Several patches of recently exuded lymph were present on the outer surfaces of the ventricles. The weight and size of the heart were greatly increased. The right cavities of the heart were relaxed and filled with dark fluid blood and a chicken-fat clot. The left side of the heart was less relaxed, and contained a smaller quantity of blood. The wall of the right ventricle is nearly twice its usual thickness; its cavity is slightly enlarged. The right auricle is dilated. The valvular curtains at the pulmonary orifice appear competent, and show no inflammatory deposits. Tricuspid valve slightly incompetent, otherwise normal. The left auricle, with its appendix, is enormously dilated. The left ventricle is concentrically hypertrophied. The aortic valve curtains are somewhat thickened, but they are competent, and do not encroach upon the orifice. The mitral curtains are adherent to each other along their entire right borders, and along the external portion of their left free margins, thus leaving a space only four millimetres long by two wide for the blood to pass through. The valve has a leathery feel, but neither it nor the surface of the auricle is rough. The mitral valve does not present the funnel-shaped appearance usually seen in such cases, because, probably, the curtains had adhered to each other irregularly, and left the small opening to one side of the centre of the normal orifice. The lungs were dark, deeply congested, and more or less œdematous. Several ounces of clear serum were found in the peritoneal cavity. Liver, spleen, and kidneys dark and congested.

One point in the clinical history of this case is worthy of special attention. The first symptoms, directing attention to cardiac disease, were the rapid pulse and exceedingly irritable condition of the heart. These symptoms existed for several weeks, and probably for a few months, before a murmur was audible. An explanation of these, without the presence of a murmur, will be found by a careful study of the diseased mitral valve before us. Neither the valve nor the surface of the auricle is roughened, consequently, for the production of a presystolic murmur under such conditions, it is necessary for the blood-current to meet with sufficient resistance in its passage from the auricle into the ventricle to enable it to set up decided vibration in the valve itself. Before sufficient mechanical obstruction took place at this orifice, the parts being comparatively smooth, to develop a murmur, inflammation and beginning adhesions of the curtains to each other were taking place. The latter conditions, although not sufficient to give rise to a murmur, rendered the heart irritable. If the explanation given is the correct one, it points to the significance of some irritable hearts, where no murmur is present to announce cardiac valvular disease. The length of the murmur was greater than that of any mitral presystolic murmur that I had heard before. It seemed to be divided into two parts, both occurring between the diastole and systole of the heart. The first part was the softer, and had less intensity; the latter was very rough, and ended abruptly. They corresponded to what Hayden has described as the post-diastolic and presystolic murmur. He says they always denote great obstruction at the auriculo-ventricular orifice. The post-diastolic murmur, he thinks, is due to the passive flow of blood from the auricle into the ventricle, the presystolic taking place when the auricle contracts. If subsequent autopsies should almost constantly associate the prolonged or double presystolic murmur with great stenosis at the mitral orifice, it will be of value in prognosis, as life cannot long continue when stenosis is as great as seen in the heart I exhibit to-night.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, June 6, 1883.

The President, Alfred Stillé, M.D., in the Chair.

Dr. J. M. Keating made

SOME OBSERVATIONS ON THE SALIVARY DIGESTION OF STARCH BY INFANTS.

Recently, in a late English work, he said, I find the following: "During the first few months, farinaceous food of every kind should be avoided, for the child's stomach (?) cannot digest it. Until the third month, or even later, no saliva is secreted, and without this floury foods cannot be assimilated." (*Management of Infants, etc.*, by Howard Barrett.) This idea is so prevalent, and most of us have adopted the statement as representing the teaching of physiologists, that it has always been a matter of surprise to those interested in the feeding of infants to find occasionally, especially among the poorer classes, infants fed upon corn-starch or other farina, almost to the exclusion of other food, and thrive.

At present, we presume that amylaceous material has of necessity to be converted by hydration into glucose, and for this reason I will not detain you by indulging in the more speculative aspect of this subject, as to whether dextrine is capable of being absorbed, and which of the two ferments, that of the salivary glands or of the pancreas, is of the most importance.

We have left this matter for further investigation. Prof. Albert R. Leeds, in his very able *exposé* of the subject of foods as regards their chemical constituents, made the matter so clear, that in his table of the analyses we have evidently an accurate guide for the selection of food in individual cases. But as the general belief is that for infants of a tender age our choice should fall on that which contains a minimum quantity of starch and a maximum amount of vegetable albuminoids, or foods, based on the Liebig formula, I deemed it valuable to institute a series of experiments, the result of which I confess were rather surprising, to test the saliva of infants, and to satisfy myself that the reason why some infants apparently thrive on starchy food is not due to any change in the starch in its preparation, but depended upon contact with secretions well established in childhood.

In these tests we endeavored, as far as possible, to exclude all error. Corn-starch was used, it having been previously boiled, cooled into a paste, and portions of this were put into little linen bags, and given to infants to suck for two minutes at a time; Pavy's test was then used; the corn-starch paste exhibited before the experiment no evidence of sugar change.

The linen was thoroughly boiled without discoloration of the solution. The bags with their contents were in each case thrown into a test-tube, and I submit for your examination the accompanying report.

To the resident physicians of the Philadelphia Hospital, Drs. B. F. Hawley and A. E. Roussel, I am indebted for assistance in this matter, as many of these tests were repeated a number of times by them, and great care was used to insure accuracy. My report includes the results obtained by experiments with the saliva of twenty-one children—varying in age from six days to seventeen months. The sugar-change was noted in all but three—one of these was a babe six days old, whilst in another babe seven days old a marked reaction was observed. I feel satisfied that some infants do digest starch provided it is presented to them in a digestible form, and also that the salivary secretion which occurs earlier than we have been accustomed to believe, is allowed to come in contact with it, and I cannot but attribute the many statements to the effect that starchy food in small quantities is contraindicated, to the fact that the secretions of the mouth are less liable to exert their influence when such food is administered by bottle and deposited in a surprisingly short time in the acid juices of the stomach. If starchy food, such as barley flour, oatmeal, rice, wheat flour, etc., is indicated on account of its highly nutritious qualities which exist in all portions of the grain and deemed advisable in the feeding of children, our few observations teach us that they should be administered in such a way as to insure their thorough digestion, and I am satisfied that the surprising results we witness, especially among the poor, of thriving table-fed babes, is due to the mode of feeding more than to the fact that they are exceptional and astonishing cases. My table shows that the age of the infant is not a guide to the quality of its saliva, and we should bear this in mind when choosing the form of food. Thus, should we be called upon to regulate an infant's feeding, it would be important for us to test the saliva.

If we find a sugar change taking place, we might incorporate with milk small quantities of one of the cereals, either barley, oatmeal, or wheat. On the contrary, should the test prove negative, Horlick's or Mellin's food would be decidedly preferable. But, while thoroughly convinced that the saliva is a most important element in digestion, we cannot overlook the fact that starchy foods have also to run the gauntlet of the pancreas, which organ, if it possess in childhood relatively the same power that it does in latter years, is far more active than the salivary glands. We cannot, then, overlook the value of a microscopic examination of the stools of all bottle-fed children, for I believe that by this alone we can regulate the quantity of farinaceous food, detecting the proportion of the undigested residue.

The following are my conclusions:

The saliva of some infants possesses the property of converting starch into glucose, regardless of age.

The age of the infants cannot be taken as an indication of this property of its saliva.

When such a condition is found to exist, a small quantity of well-prepared farinaceous food is valuable as an element in the diet, incorporated with mixed cow's milk.

An examination of the stools of children so fed would be a guide as to the quantity of starchy food to be used, and when farinaceous food is employed, slow feeding is probably preferable to the bottle.

DR. N. A. RANDOLPH, Assistant Demonstrator of Physiology in the University of Pennsylvania, then read the following

NOTE ON THE FECES OF STARCH-FED INFANTS.

The series of experiments presented in the preceding paper by Dr. Keating seems to me to be in the highest degree suggestive, for it is only rational to suppose that the development of the amylolytic ferment of the pancreatic juice is coincident with the appearance of the analogous salivary ferment. Inasmuch, however, as the food even in spoon-fed infants is retained but a short time in the mouth, and further, as the continued action of the saliva after it enters the stomach is as yet problematical, the only absolute control for such observations is afforded by an examination of the feces.

Through the kindness of Dr. Keating I have been enabled to examine the stools of twenty-four starch-fed infants, of ages varying from forty-five days to eighteen months. Twenty-three of these children were fed upon cracker-dust, water, and condensed milk. The twenty-fourth received corn-starch boiled in milk.

The freshly evacuated feces of each infant were carefully bottled and labelled, and a drop of a solution of iodine was added to a small portion of each specimen, which was then submitted to microscopical examination. Besides turning the starch blue, and indicating the presence of dextrine by a peculiar mahogany-red color, the iodine has the advantage of rendering any fats which may be present much more readily apparent. The reaction of each specimen was taken, but though this varied from acid to alkaline and neutral, no correlation between the reactions and the other properties of the specimens could be observed. A decoction of each was tested for glucose with freshly prepared Fehling's solution, but except in one instance no appreciable amount could be found.

The presence of *starch* was exceptional and apparently in no degree dependent upon the age of the child. The stools of eighteen out of the twenty-four children contained either no starch, or but a trace, *i. e.*, no more than is frequent in the evacuations of a healthy adult upon a mixed diet. Six of these specimens were from children of three months or less—the youngest being but forty-five days old. In many cases the broken and empty cellulose envelopes of the starch granules were clearly discernible.

The six infants in whose evacuations a noteworthy amount of starch was present, were aged respectively three, four, ten, thirteen, fourteen, and seventeen months. The eldest two were in very bad health.

The following is a tabular statement of the age, diet, and appearances of the feces in the children forming the subjects of this study.

An Examination of the Feces of Twenty-four Starch-fed Infants.

No.	Age	Food	Starch present.	Remarks.
1	[illegible]	Condensed milk and cracker dust.	None.	
2	[illegible]	"	Traces.	
3	[illegible] "	"	"	
4	3 "	"	"	Twice examined; no fat before inunction, about 10 per cent. after.
5	3 "	"	"	
6	3 "	"	About ¼ starch.	
7	3 "	"	Traces.	
8	4 "	Corn starch and milk.	"	
9	4 "	Condensed milk and cracker dust.	None.	Many broken cellulose envelopes.
10	4+ "	"	Traces.	Evidences of potato surreptitiously given.
11	5 "	"	About ½ starch.	
12	5+ "	"	None.	
13	5+ "	"	"	Many bacteria.
14	6+ "	"	"	10 per cent. fat; had had inunctions.
15	8+ "	Breast and cracker food.	Traces.	
16	10+ "	Condensed milk and cracker dust.	More than normal.	Many bacteria; evidence of potato surreptitiously given.
17	13— "	"	20 to 30 per ct.	Some glucose present, and indications of dextrine; saliva was found to be inefficient.
18	14— "	"	Traces.	
19	14 "	"	"	
20	14 "	"	10 p. ct. starch	Sick.
21	14+ "	"	None.	Except a few large cells containing starch from potato.
22	17— "	"	"	
23	17— "	"	Over ¾ starch.	Syphilitic; saliva was found to be inefficient.
24	18	"	Traces.	Indications of dextrine.

The facts presented appear to justify the following conclusions:

First, that *many* infants of under three months can digest starchy foods.

Second, that the individual variations in this regard are so numerous that no broad and general statement can be made as to the period at which infants *begin* to digest starches; and

Third, that the physician can be absolutely certain that a farinaceous ingredient in the diet of a young infant is beneficial only by an examination of the dejecta under such diet.

After the reading of the preceding paper,

DR. KEATING spoke of one case in which fat was found in the feces—cod-liver oil had been administered in the form of inunctions, and the child fed alone on Borden's condensed milk.

DR. RANDOLPH replied that he had found 10 per cent. of fat in the feces of a child which was receiving two inunctions of cod-liver oil daily. He was now conducting some experiments upon this subject, and intended to report the results to the College in a communication to be read at a future day.

CORRESPONDENCE.

THE PROPHYLACTIC TREATMENT OF DIPHTHERIA.

To the Editor of THE MEDICAL NEWS.

SIR: In THE MEDICAL NEWS of June 30th, Dr. F. P. Porcher recommends a prophylactic treatment for diphtheria, which I fully endorse.

On the 21st of July, 1879, I was called to a case of diphtheria, which was the first of over one hundred cases of the disease which occurred during an epidemic in this vicinity.

The type proved to be very malignant, seven cases were fatal, and died within eighteen hours of the first noticeable symptoms; one as early as six hours; five were left completely paralyzed; four of the five recovered; one died from strangulation while eating.

The treatment used, was tr. mur. iron, chlo. potash, and quinine, given very freely with a liberal allowance of milk punch and eggnogg.

The disease proving very malignant, I put the children in the infected district on the above medicines as a prophylactic. In the houses where the disease proved malignant, I gave it every three hours. Among those who were taking the medicine, but one case of the disease developed, and that case was taken sick within twenty-four hours after the first dose of medicine was given.

In the infected houses where the children were taking the prophylactic, there were twenty-five cases among the adults, who were taking nothing to prevent the disease. If the medicine did not protect the children, why did they escape and the adults take the disease?

Yours respectfully,
J. L. NAPIER, M.D.

NEWS ITEMS.

NEW YORK.

(*From our Special Correspondent.*)

SANITARY INSPECTION OF TENEMENT HOUSES.—On July 9, the Board of Health appointed fifty physicians, who, as temporary assistant sanitary inspectors, are to form the summer corps for the purpose of visiting the tenement houses of the city, and treating any sick children that may be found in them. The city has been divided into fifty districts, and each inspector, during his service of two months, was instructed to visit each house at least twice during that time. Prescriptions, which are advised to be as simple as possible, will, in case the parents are too poor to pay for them, be filled at the Dispensary of the Health Department. Where it is deemed advisable, tickets will be given for the Floating Hospital and the Seaside Nursery. Printed directions regarding the care of infants and on sunstroke are also to be distributed. Dirty houses and streets are to be reported to the Board. The salary is $100 a month.

THE RESIGNATION OF DR. DALTON.—Dr. John C. Dalton, the well-known physiologist, has resigned his position as Professor of Physiology at the College of Physicians and Surgeons which he held for so many years. He will be succeeded by Dr. John G. Curtis, who, for several years past, has been the adjunct professor. Dr. Dalton's resignation is very generally regretted.

WASHINGTON.

(*From our Special Correspondent.*)

THE UNITED STATES AGRICULTURAL DEPARTMENT AND THE STUDY OF THE GERM THEORY OF DISEASE.—The Agricultural Department has availed itself of the services of Dr. D. V. Salmon, D.V.M., and has established an experimental farm of seven acres—lying on the eastern outskirts of Washington—with facilities for the proper study of the pathological appearances in the diseases of fowls, swine, and cattle, and for the study of inoculation as a preventive of contagious fevers. Dr. Salmon will be assisted by Dr. Rose, who will reside on the farm and devote himself to the treatment and clinical care-taking and make the post-mortems, while Dr. Salmon, at the Agricultural Department proper, will pursue his investigations in the microscopical appearances in the blood of these diseases, and the cultivation of the virus—its attenuation and use in inoculation. Dr. Salmon has already made marked advances in this direction and published such results in our journals (*The American Monthly Microscopical Journal*, April, May, 1881, July, 1882), and in his reports to the Commissioner of Agriculture—as to call forth high praise from those who have followed his investigations. Dr. Sternberg considers that if his work had been done anywhere else than in America, it would doubtless have attracted more attention, both at home and abroad.

Dr. Salmon began his investigations of inoculation in the summer of 1880, and selected fowl cholera. He extracted the blood directly from the heart, using all the means possible to avoid the introduction of foreign germs, and cultivated the germs found in a broth made from the flesh of fowls, which was filtered until limpid, and then sterilized by heat. He gives this process at some length in his published reports. His fluid is an infusion of muscle at the temperature of 160° F., and for three hours boiled, filtered, and neutralized in caustic soda, and his sterilizing apparatus he thinks well adapted to its purpose. Test-tubes are prepared against contamination, half filled with the cultivating fluid; the blood introduced, tightly corked with rubber, which is provided with a bent ventilating tube, tightly packed with cotton, and placed in a vessel containing three or four inches of water that can be tightly covered; this is boiled three or four times, at intervals of a few hours. He makes the positive assertion that prolonged boiling is necessary to proper sterilization. His experiments with a steaming apparatus have not proved satisfactory. He alternates his views by successive dilutions, and considers that his process facilitates exactness in the amount employed, in rapidity of preparation, and in the preservation of the virus for as long a period as possible.

The inoculation is done with a grooved lancet, puncturing between the skin and the muscles of the wing. He found decided evidences of individual susceptibility; thus, one bird died after inoculation with a high dilution of 1 to 40,000, while another resisted a drachm of the pure virus. After these inoculations, there were local lesions, with rise of temperature; but on their restoration to health, they were tested with strong virus, and placed in infected runs with sick birds, but resisted all contagion. Eighty birds had been so inoculated with success at the date of writing.

The virus itself he gives as a form of micrococci, readily obtained by a fresh solution of aniline violet, prepared in strong alcohol, 1 grain to ʒij of aq. dest., and used at once; and he objects to Klein's apparatus as subject to varying temperatures, which varying temperatures result in the appearing of a different organism, as was admitted by Wood and Formad in cultivating diphtheritic virus, his cemented cell with a thin cover not being sufficient for proper sterilization, and the fluid—the aqueous humor of a rabbit's eye—was not sterilized. The virus is not diffusible through the air, but appears in the excrement, is taken in through the alimentary canal, and the germs are not preserved in the earth as long as six months. In charbon the virus is retained for years by the earth.

He accounts for the failure to discover the bacillus anthracis in the blood, in cases of charbon, after inoculation, as being due to the fact that the virus takes time to work its way from the lymphatics of the skin through the glands to the blood, and that consequently death may occur from chemical poisoning before the bacilli have reached the blood in any appreciable quantity, but that even then they may be cultivated from this blood. His answer to Bert's experiments, of having destroyed the bacilli with compressed oxygen and alcohol, and still found a virulent fluid, from a formless ferment, is that there were live spores remaining which could be cultivated into bacilli. He attaches much importance to Chauveau's success in inoculating with diluted charbon virus on sheep, and to Pench's similar experiments with sheeppox.

In the swine plague Dr. Salmon, contrary to the observations of Klein, gets no bacilli, but does get many micrococci, which, when cultivated and inoculated, resulted in an eruption and elevated temperature. He concludes, therefore, that the reason Klein did not obtain more positive results was that he did not obtain the germ, and calls attention to the fact that Klein did find micrococci and not bacilli in the tissues of the affected animals. Pasteur gave this same view in 1882, but Salmon is quoted as having so expressed himself in the *Agricultural Report* for 1880.

Such experiments as these, made by a department of our Government, bring its operations directly in the range of the intelligent medical practitioner.

DR. JOHN A. OCTERLONY has been recently elected Professor of Obstetrics and Diseases of Women and Children in the University of Louisville, in place of Dr. Theophilus Parvin, recently elected to the Chair of Midwifery in Jefferson Medical College.

THE PRESIDENT OF THE ONTARIO MEDICAL ASSOCIATION.—At the annual meeting of this Association held in June last, Dr. Daniel Clark was elected *President*, and not "Dr. W. Clark," as by mistake stated in our issue of June 23d.

THE ST. LOUIS MEDICAL SOCIETY AND THE CODE OF ETHICS.—In reference to the preamble and resolutions offered by Dr. Pollak at the late meeting of the American Medical Association, the St. Louis Medical Society has adopted the following resolution:

That the St. Louis Medical Society distinctly repudiates the statements contained in said preamble and again expresses its fealty to the existing Code of Ethics as a time-honored and most suitable fundamental law of the profession, and specially depreciate any action calculated to reflect upon its loyalty to those principles which have heretofore secured immunity from the machinations of schismatics within or enemies without.

The Michigan State Board of Health.—The regular quarterly meeting of the Michigan State Board of Health was held at Lansing, July 10, 1883. The Secretary read his report of work during the last quarter, which showed that a successful sanitary convention had been carried on at Reed City, and arrangements had been made for a convention at Muskegon, August 23d and 24th; that considerable correspondence had been had concerning the examination of plans for proposed buildings at various State institutions; that the report for 1882 had been distributed to various societies, libraries, etc.; that the weekly bulletin of health in Michigan had been regularly prepared and issued; that returns of the names and addresses of about 1200 health officers had been received and filed; that a circular relative to the danger to be anticipated from smallpox, and one relative to the reporting of contagious diseases with appropriate blanks, had been devised and distributed to all local boards of health; that the article entitled "Diseases in Michigan in 1882," had been compiled; that the accumulated letters of the office for the years 1873 to 1881 had been arranged and bound; that the compilation of the articles on "Meteorology in Michigan in 1882," and on "Weekly Reports of Diseases in 1882," was well in hand; that circular 55, relative to the work of health officers, had been revised to conform to the new legislation of 1883, and, if approved by the Board, was ready for publication. The Secretary read a *résumé* of the recent work of other State Boards of Health.

The Board then proceeded to examine plans for proposed public buildings, under the law which requires all plans for State buildings to be submitted to the State Board of Charities, and to the State Board of Health. Plans were examined in detail as follows: For wings to the present school for the blind, at Lansing; for a proposed hospital at the Michigan Asylum for the Insane, at Kalamazoo; for a cottage hospital for the State Public School, at Coldwater; and for a main building for the State Industrial School for Girls, at Adrian, and made record of propositions which were approved, and several recommendations.

On motion of Dr. Lyster, the State Board's Committee on Buildings, including ventilation, etc., was requested to prepare a report on the best plans and methods of construction of hospitals suitable for the various State institutions.

Gastrostomy.—Mr. J. Greig Smith reports a case of gastrostomy for malignant stricture of the œsophagus, the patient also having a hydatid cyst of the liver.—*Bristol Medico-Chirurg. Journal*, July, 1883.

The Grocer's Company Prize.—The Court now announces as the subject for competition for the prize of £1000 the following problem: "To discover a method by which the Vaccine Contagium may be cultivated apart from the animal body, in some medium or media not otherwise zymotic; the method to be such that the Contagium may by means of it be multiplied to an indefinite extent in successive generations, and that the product after any number of such generations shall (so far as can within the time be tested) prove itself of identical potency with standard Vaccine Lymph." The prize is open to universal competition, British and foreign. Competitors for the prize must submit their respective treatises on or before the 31st of December, 1886; and the award will be made as soon afterwards as the circumstances of the competition shall permit, not later than the month of May, 1887. In relation to the Discovery-Prize, as in relation to other parts of the Company's scheme in aid of sanitary science, the Court acts with the advice of a scientific committee, which at present consists of the following members: John Simon, C.B., F.R.S., John Tyndall, F.R.S., John Burdon Sanderson, M.D., F.R.S., and George Buchanan, M.D., F.R.S. All communications on the subject as to conditions, etc., are to be addressed to the Clerk of the Grocer's Company, Grocer's Hall, London, E.C.—*Edinburgh Med. Journ.*, July, 1883.

Dr. Spina, assistant in Professor Stricker's laboratory, at Vienna, who has recently been prominently before the profession in opposition to Koch's theory of the bacillus tuberculosis, has been nominated Professor of General and Experimental Pathology at the University of Prague.

Health in Michigan.—Reports to the State Board of Health for the week ending July 7, 1883, indicate that intermittent fever, cholera infantum, remittent fever, diarrhœa, dysentery, and bronchitis have increased; and that inflammation of bowels has decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria and scarlet fever were each reported present during the week ending July 7, and since, at 10 places; and measles at 15 places. The last case of smallpox (in Kalamazoo Township) was reported dismissed July 7.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 9 TO JULY 16, 1883.

Baily, E. I., *Colonel and Surgeon.*—In addition to his present duties, to take charge of the Office of Medical Director, Military Division of the Pacific, during the absence of the Medical Director.—*Par. 2, S. O. 64, Military Division of the Pacific, June* 30, 1883.

Campbell, John, *Lieutenant-Colonel and Surgeon, Medical Director, Department of the South.*—Leave of absence on Surgeon's certificate of disability, granted by S. O. 50, Department of the South, May 21, 1883, extended one month, on Surgeon's certificate of disability, with permission to leave the Department of the South.—*Par. 7, S. O. 156, A. G. O., July* 9, 1883.

Magruder, D. L., *Lieutenant-Colonel and Surgeon, Medical Director, Headquarters Department of the Missouri.*—Granted leave of absence for one month, with permission to apply for an extension of one month.—*S. O. 145, Department of the Missouri, July* 12, 1883.

Sutherland, C., *Colonel and Surgeon, Medical Director, Military Division of the Pacific.*—Granted leave of absence for one month, with permission to apply to the Adjutant-General of the Army for extension of two months.—*Par. 1, S. O. 64, Military Division of the Pacific, June* 30, 1883.

Perley, Harry O., *Captain and Assistant Surgeon.*—Assigned to duty at Fort Pembina, D. T.—*Par. 1, S. O. 118, Department of Dakota. July* 5, 1883.

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

EXSECTION OF THE HIP-JOINT.

A Clinical Lecture delivered at Bellevue Hospital Medical College.

BY LEWIS A. SAYRE, M.D.

(Specially reported for the MEDICAL NEWS by
EDWARD DEVELIN, M.D.)

GENTLEMEN: This man, M. M. D., æt. 37 years, was brought to my office a few hours ago by Dr. Barnes, of Binghamton, N. Y., who gave me the following history: Both parents and family are healthy. Patient was strong and robust until two years ago, and has been living on a farm; while ploughing, he has been in the habit of kicking the mud off the plough, and by this means the hip-joint has been injured, which has resulted in inflammation, and at the present time it has reached the stage of suppuration, with exfoliation of bone.

The patient has been wearing this long hip-splint, which is of the pattern of the first splint I devised, and which I have since condemned. Here you will observe that instead of the pelvis belt completely encircling the pelvis, it passes round but one-third of a circle, and to this is attached one perineal band, which passes under the perineum upon the side of the diseased limb; by this means the perineal band is brought more towards the diseased joint, instead of passing directly up over the pubes, as in my improved splint; by the bands passing directly up over the pubes, it lessens the liability to strangulation of the circulation, and at the same time the weight of the body passes down directly in the centre. All the instruments I have made for the past ten years are made with a complete pelvis belt, with two perineal bands. It is well for you to remember that the perineal bands pass directly up in front of the pubes, but posteriorly they are wide apart, coming across the glutei muscles; the great difficulty being that the instrument-maker will place them widely apart anteriorly, in spite of all instructions that I have given to the contrary. It is very essential that the bands be near together in front for the reason that has been already stated.

As soon as I have discovered an improvement in the construction of any of my instruments, I denounce the instrument previously made. I do not blame any gentleman living away from the cities, and who perhaps is unable to secure information upon this point as easily as those living in a large city; it is the instrument-maker who is at fault, as it his special calling to make instruments according to the most improved plan, and he should certainly know better than to offer for sale those that have been condemned.

As we continue our examination, you will observe that the right limb is two inches shorter than the left, although the limb is perfectly straight owing to Dr. Barnes' careful method of applying the extension. You will observe that there is one sinus in the groin, one below the crest of the ilium, one above the trochanter major, and another about three inches below; we have in all, four sinuses, and judging by appearances, they lead to dead bone; this you may know by their peculiar characteristic appearance, which is graphically described as representing the anus of a chicken. This dead bone is a source of irritation, and keeps up a constant discharge from the body, emptying itself by way of these sinuses. As time goes on, granulation commences around the borders of these orifices, and becoming exuberant, is recognized as proud flesh; in this case you will observe it presents this appearance.

Whenever you find an opening of this description in such a case as is here before you, you may be certain that such an opening leads to dead bone; you may be positive upon this point. In probing these sinuses, a flexible probe should be used in order that it may follow the channel without injuring the tissues; never use any force while probing at the seat of disease. The question here is what to do in this case; nature herself is trying to exsect the hip-joint; if the patient does not succumb from the long process of suppuration, we often get remarkable results from nature's treatment; in fact, there are some gentlemen to-day who claim that this is better than surgical treatment; I must confess that I differ from that doctrine.

Here now is dead bone, and there is no hope for that man to get well until that bone is removed; now in the slow process of nature to remove that dead bone, there is a long travelling of pus through various roads which it must make for its exit; at the same time more or less of that pus will be absorbed by the system, resulting in anæmia and exhaustion. The patient informs me that while the sinuses are open and there is a free discharge of pus, he feels much better and his general health improves; this is because the poison of the broken-down tissue is not absorbed by the system, but when the openings become closed as they are apt to do for a short time, there is no escape for the pus, and hence it is returned to the system, and as a natural result constitutional disturbance ensues, followed by loss of appetite, with febrile movement, etc. This process may go on until all the diseased tissues have been thrown off, if the man can outlive the disease, but this can hardly be called the rule.

The question now arises as to the advisability of complete exsection of the bone, and the application of a drainage-tube to the wound. My own experience is that where the disease has gone on to caries of the bone, and where you have relieved the parts from reflex action, and yet the inflammation still goes on to destructive caries, that notwithstanding your extension and proper adjustment of the parts to give the patient ease, and afford him the benefit of the open air for the improvement of his general health; that notwithstanding the drains are placed in such a manner as to give free outlet to the pus; if, I say, that in spite of all these precautions the carious degeneration still goes on, then your duty is promptly to remove the diseased tissues by an operation.

If, on the other hand, the caries diminishes and the discharge from the sinuses becomes gradually less, under your precautionary measures, then you should be satisfied with your expectant treatment.

In one case of hip-joint disease Dr. Spencer removed nine inches of the femur subperiosteally, and recovery commenced from the instant, which resulted in a shortening of the bone of only three inches, with a good movable joint.

In this case by making pressure into the joint severe pain is induced, but there is a total absence of pain immediately that extension is applied.

I am very glad to find that this limb is dressed in a proper manner, extension being made from the thigh and not from the leg alone. To illustrate this point in regard to the proper mode of extension, I can do no better than relate an incident that occurred when visiting London for the first time: A child was brought to me suffering from hip disease and in much the same condition as this man, and upon whom extension had been applied *from below the knee;* I took the child in my arms, and laying the diseased limb over one of my arms in such a position as to immediately relieve the diseased surfaces from pressure, and upon the instant the expression of the child's face turned from that of pain, to relief and contentment. When I removed the strips of adhesive plaster from the leg, one of the gentlemen present checked me, and stated that they had been following out the method of extension by making traction below the knee by the use of the adhesive plaster and roller bandage; I informed the gentlemen present that the treatment had been entirely wrong, and that instead of making traction upon the thigh, they had simply been making traction upon the ligaments of the knee-joint.

At this point Mr. Berkley Hill arose and said: "Gentlemen, I desire to explain to you why we have had such bad results from treating disease of the hip-joint according to the American plan. You must all remember the number of diseased knee-joints we have had following the treatment of the disease of the hip-joint; we have produced disease of the knee-joint by our constant traction upon the ligaments of this joint, and have thus complicated the disease already existing as just described by Dr. Sayre. I think it most remarkable that we should not have thought of it, and I thank you, Dr. Sayre, for coming here to tell us of our mistake."

A more straightforward acknowledgment of an error I have never seen. At a future time I will present this patient before you, and state the treatment required in this case.

(The patient again before the class at the following clinic.)

We now propose to dilate these various sinuses and ascertain the precise condition of the bone, as to whether we shall perform the operation of exsection. Mr. Anthony White was the first one to perform this operation, in 1821; you will find a full account of the case in Cooper's *Surgical Dictionary*. Dr. Bigelow, of Boston, performed the operation in 1852, the patient dying twelve days after. I performed the first successful operation in this country in 1854. I had been called to see the child two years before; at that time I recommended removal of the bone. I explained to the father that the hip was full of diseased bone, and that the numerous sinuses from which pus was issuing strongly indicated the necessity of an operation. He therefore consented, and I arranged for the operation to take place upon the day following. Drs. Cheeseman, Rogers, and Hoffman were the three medical gentlemen called in consultation; they condemned the operation so violently that the father came to me, and the result was the operation was postponed. I did not hear from him again until two years after, when he called upon me and said that he had been unable to find one doctor who agreed with me, but inasmuch as the child was daily becoming more exhausted, he and his wife desired the operation to take place at once, to save the child, if possible, if I could find one medical gentleman who would agree with me as to the opration. I therefore notified Drs. Parker, Hoffman, Cheeseman, and the late Jas. R. Wood, to attend and see the operation, but not one of these gentlemen would go. The operation at that time was so unknown that hardly any one would risk his reputation by even being a witness to it. Dr. Drake, a retired physician, however, said he would like to see the operation, provided I would not hold him responsible. It proved a complete success in every way; the patient is now married and has a family; there is a little deformity with a shortening of half an inch, but there is quite considerable motion at the joint. When I reported that case and reported having motion I received a great deal of ridicule and censure. I then had the child taken down to Dr. Wood's office and there examined carefully, and proving the truth of my remarks. This, of course, stopped all further discussion upon that point.

In making your incision, it is very important to take a point midway between the anterior superior spinous process of the ilium and the trochanter major; that will bring you just over the top of the acetabulum; you then take a firm, strong knife, and plunge directly down until the knife touches the bone; then draw your knife down to the top of the trochanter major; then curve it inward, making your incision from four to eight inches, according to the extent of the bone diseased. You must be sure and make your incision *through* the periosteum. You then take a curved, probe-pointed bistoury, and make an incision through the periosteum only, at right angles to your previous incision, and at a line with the trochanter minor; then, with the periosteal elevator, peel up the periosteum from the diseased bone until you come to the digital fossa, where the rotator muscles of the thigh are inserted; here it may be necessary to use your knife, to carefully cut them off from the bone itself. After having peeled off the periosteum in this manner, the limb is to be adducted, and the diseased bone removed by a chain or small thumb-saw. If you find that you have reached healthy bone, your object is accomplished; but if, on the contrary, you find that there is yet diseased bone remaining below your section, it must be removed, perhaps necessitating a larger incision. It is, however, an absolute necessity that all dead bone be removed, to make the operation a success.

Sometimes by passing the finger into the rectum you can determine to a certain extent to what degree the caries of the acetabulum has progressed, and if the head of the bone be in its place. My assistant informs me that the internal periosteum points to great thickening of its substance. Here passing a probe into one of these sinuses, it passes in to the extent of eight inches, and I cannot say how much further it may go. Under these conditions, and discovering a large amount of pus and dead bone within the joint, exsection of the hip-joint has been determined upon.

The disease in this case being in the right thigh, it is necessary for me to stand on the left side of the patient. I shall make my incision connect these various sinuses, it being always advisable to follow this method when feasible. I therefore, as you observe, press the knife down at the point indicated, until I reach the bone, and I now make my curved incision. A broad curved spatula is now placed in either side of the wound, to hold it open; and upon further examination, we find the periosteum to be very much thickened. I now take this probe-pointed bistoury, and make my incision through the periosteum, half encircling the femur at a point below the trochanter minor, and then taking this periosteal elevator, I endeavor to peel off the periosteum; remember, it is very necessary to leave as much of the periosteum as possible; and now reaching the digital fossa, we divide the rotator muscles. Having peeled off the periosteum, I now take this small thumb-saw, and make my section below the trochanters, and with the aid of these lion-forceps withdraw the head, neck, and trochanters of the femur *en masse*. The acetabulum I find to be necrosed, and completely perforated to the internal periosteum, this, however, being intact.

Now although I have removed nearly five inches of this man's femur, I find that the bone is diseased still further down. I therefore peel off the periosteum still lower and my assistant pushing the shaft of the femur upward toward the wound, bringing the bone more fully into view and thus enabling me to remove the necrotic portion with greater facility, I find it necessary to remove another inch of the shaft in this case; this being done, I remove carefully as much as possible of the dead bone from the acetabulum and portion of the pubes which I find is also necrosed; the latter, however, is a somewhat difficult matter owing to the close proximity of the femoral artery to the diseased structures. The wound is now thoroughly washed out with a carbolized solution of a strength of one to forty.

The operation itself is very simple as you observe, but the after-treatment is extremely important, the whole secret of your success depends upon this. My assistant now carefully holds the diseased limb for fear of injuring the artery while the patient is placed in the wire cuirass, this being a wire cradle made to fit the patient with movable foot-pieces by which your extension can be maintained. I now fill the wound with Peruvian balsam, manipulating it in such a manner that it penetrates to all parts of the cavity in every possible direction. You now observe that I take this piece of oakum which is also saturated with the balsam, and carefully pack the wound in order to maintain the original shape of the periosteum, and thus as new bone is formed, it will be of serviceable thickness and strength. I now insert the drainage-tube, and put in a suture at the upper and lower portion of the wound, and endeavor to secure union of these portions of the incision by union by first intention.

You now observe that as the patient lies in the cuirass, the anus is directly over the opening posteriorly, thus allowing of free evacuations without soiling the instrument. The whole secret is to secure the sound limb as a means of counter-extension; first fastening the sound limb to the leg-piece with a roller bandage, commencing at the foot, and as you reach the knee, place a folded newspaper over it to prevent flexion; then passing your bandage around the thigh, and as you reach the perineum, bring your bandage from the perineum over the handle of the instrument at the side, by which means your counter-extension is secured.

Having now fastened the sound limb in this manner, we apply our extension straps of adhesive plaster to the diseased limb, making the extension from the thigh and never from the leg alone in these diseases of the hip-joint; these straps, you observe, are secured in the ordinary manner with the roller bandage; and the foot is now secured to the right foot-piece of the instrument, and by means of this screw at the bottom the requisite extension is made. Having effected this, we now fasten the limb to the instrument with a roller bandage, carefully padding the inequalities of the limb in order to obtain equable pressure at all points. I now moisten the wound with carbolized oil, and cover it with carbolized cotton and the usual antiseptic dressing; securing the whole with a broad roller.

This dressing can be left on for twenty-four, forty-eight, or sometimes ninety-six hours, or until such time as moisture shows itself upon the outside of it. You will also notice that I pass one or two turns of the roller over the abdomen, and thus secure perfect immobility of the parts.

The pulse and respiration of the patient are now good at the conclusion of the operation, although we have removed as large a quantity as six inches of his femur.

(Patient again before the class for the first time since the operation.)

It is now some four months since you saw this patient's hip-joint exsected, and I bring him here today to show you the result of the treatment before he leaves for his home, which he is desirous of doing tomorrow. During the intervening time since you last saw him, Dr. Keyes, in whose ward he was placed, found it necessary to make another incision, and remove further portions of necrosed bone to the extent of about another inch of the femur. At the time I performed the operation, I feared such might be the case, but as the periosteum was very thin, and firmly adherent to the shaft lower down, and the diseased portion was so extremely small in amount and in the centre of the shaft, I was in hopes Nature would have eliminated that portion without further necrosis. This fact shows how absolutely necessary it is to remove all necrosed bone when operating. There are, however, some cases in which this may, perhaps, be impossible.

We find that we now have a shortening of the limb to the extent of almost four inches. My impression is that, had the extension been properly adjusted, the shortening would not have been so great.

I now intend to apply the long hip splint, in order that the man can go out of doors and secure the benefit of the fresh air. You will notice that the sinuses are yet open, the lower ones discharging slightly, but the upper one has almost ceased, but a few drops of pus passing daily. The wound itself is entirely closed. Now having applied the long splint, I commence passive motion at the joint, in order that I may create a new joint. With the assistance of his crutches, the leg being maintained in the desired position by the proper application of the splint, he can now walk around and secure the benefit of the fresh air, in the mean time nourishing him well with a generous diet in order to build up his general constitution. The disease in time becoming entirely eradicated, the length of the right limb can be equalized by the application of the high shoe. [The man now with the aid of his crutches walked around the room, this being the first time he had been upon his feet since the operation.]

Note. — The patient left for his home the second day after appearing before the class at the last clinic, stating that he had no idea he could walk so well after remaining in bed for so long.

Letter from the attending physician, Dr. F. B. Brooks, received two weeks after the patient had returned home:

"Cincinnatus, N. Y.

"Dr. Lewis A. Sayre,

"Dear Sir: Since coming from New York Mr. D. has been under my care, and wishes me to write you as to his present condition. The hip is doing well, drainage perfect, and everything lovely except a slight tenderness at exit of one of the drainage-tubes. Any suggestions in regard to the case will be thankfully received. Yours truly,

"F. B. Brooks."

Extract from letter No. 2, received thirteen days later:

"Cincinnatus, N. Y.

"Lewis A. Sayre, M.D.,

"Dear Doctor: I wish to address another letter to you in regard to Mr. D. The hip is doing well with the exception of a local tenderness at exit of drainage-tube, and I find this is caused by fungous granulations. I have applied the nitrate of silver, as you directed in your letter, but as it was only yesterday I cannot yet state results.

"Otherwise he is doing well, gaining flesh, pulse regular and strong, appetite excellent, and skin good color. I would be glad to hear from you soon.

"Very truly, yours,

"F. B. Brooks."

On receipt of this first letter I advised the application of nitrate of silver to the edges of the wound, as I surmised that the slight tenderness spoken of was owing to excessive granulations. The second letter proved my suspicions to be correct; since the receipt of which I have received no further details in relation to the case from Dr. Brooks.

ORIGINAL ARTICLES.

RAPID CURE OF POPLITEAL ANEURISM BY THE USE OF THE ELASTIC BANDAGE. TWO CASES, WITH REMARKS.

BY J. T. BOUTELLE, M.D.,
OF HAMPTON, VA.

ABOUT the first of February, 1883, I was consulted by a mulatto, thirty-five years of age, for a painful tumor of the knee, which proved to be a large aneurism, filling the popliteal space, bulging on both sides, and pulsating strongly. Pulsation could be felt in Hunter's canal. He was decidedly averse to any cutting operation. While I was debating in my mind what method to pursue, I happened to meet Dr. H. M. Nash, of Norfolk, Va., who mentioned in conversation that he had produced a speedy and lasting cure in a similar case by applying the Esmarch bandage from the toes to the top of the thigh, so as to empty the aneurism by pressure, then, having compressed the femoral artery above, removing the bandage, allowing one pulsation to fill the sac with blood, and immediately stopping the artery again; afterward controlling the circulation by shot-bag pressure. I decided to try this plan, and did so; though, as will be seen, my method differed considerably from his in some of the details.

On February 8th, I proceeded as follows, assisted by Dr. J. H. Peek, of Hampton. No anæsthetic was used. The Esmarch elastic bandage was applied firmly from the toes to the head of the tibia. I then continued with one of Dr. Martin's elastic bandages—No. 1 A—winding it around the knee from the head of the tibia upward, stretching the bandage to its full extent, and proceeding very slowly, waiting a little after each turn. In this way I carried the bandage to the upper third of the thigh. After the bandage was applied, the size and shape of the tumor apparently remained the same. The pressure caused very severe pain in the knee, which the patient bore with firmness. After five minutes, I compressed the femoral artery in the groin while the bandage was removed: then the pressure was removed from the artery for one or two beats of the heart, and immediately reapplied. A faint pulsation was felt in the tumor as the arterial stream was let on. Digital pressure was kept up on the femoral artery for about fifteen minutes, then gradually slackened, and as no pulsation was felt in the aneurism, I allowed the full stream to flow through the artery. This caused no pulsation, the tumor remaining hard. A shot-bag of about ten pounds weight was suspended from the ceiling and lowered upon Scarpa's triangle; this was not sufficient to stop the circulation, but lessened its force considerably. About half an hour after the operation, severe pain came on in the ankle and shin, requiring a dose of morphine—one-half grain—for relief. The shot-bag pressure was maintained for two days, being occasionally removed for relief to the patient. Since the removal of the bandage, there has never been the slightest pulsation in the aneurism, nor any return of pain in the knee. The patient kept his bed for about ten days, and then began to walk about cautiously. In three weeks he was walking about town, and is now about to resume his occupation of cook. No œdema of foot or leg followed the operation, nor was any coldness of the limb noticed at any time. In fact, with the exception of the pain in the ankle after the removal of the bandage, which was soon relieved, he has had no inconvenience other than to keep his bed.

At my request, Dr. Nash has very kindly sent me an account of his case, which I will give in his own words:

"The case of popliteal aneurism referred to in conversation with yourself as having been successfully treated with Esmarch apparatus by myself, was that of Joseph Harris, aged about fifty years at the time of the operation—Aug. 1, 1879. The aneurismal tumor was about the size of an orange, and filled the whole popliteal space.

"On the date mentioned, the patient was etherized, and assisted by my friend, Dr. Richard Bagnall, the limb was enclosed from the toes to the middle of the thigh, and directly over the tumor, by the elastic bandage, and the tube tourniquet secured, when the rest of the bandage was removed, as is done when this apparatus is used for amputation. The tube was thus retained for nearly two hours, ether being kept up more or less all the time to cover the pain. The tube was then loosened, and the aneurismal tumor almost immediately filled with blood; and one pulsation was both seen and felt, when I at once made pressure with my thumb on the femoral above the tumor for a few minutes, after which time the tumor was, and remained, perfectly motionless, the blood which entered immediately after the removal of the tube tourniquet having coagulated. As a precaution, however, I thought it prudent to continue some pressure on the femoral for a day or two longer, which I did as well as possible under the circumstances by a bag of shot suspended from the tester of his bedstead, but which the patient's wife informed me was not kept constantly on the vessel, by reason of the pain the continuous pressure produced. Considerable œdema of the leg followed the obliteration of the vessel, which was treated by rest, warmth, and finally by a Martin's elastic bandage. The recovery was complete, and the patient has done duty as a porter since that time."

I find in THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES for April, 1881, an article by Lewis A. Stimson, M.D., on the treatment of aneurism by the elastic bandage, in which he has collected sixty-two cases, the majority being popliteal. In the number for July, 1882, of the same journal is a review of a pamphlet on the subject by A. Pearce Gould, M.S., F.R.C.S., in which the number of cases is reported as seventy-two. In these cases, although there were some differences of detail, the principle of the treatment was practically the same, viz., to maintain the sac full of blood in a stagnant condition for a considerable time until a coagulum formed. The elastic bandage was applied first to the leg below and then to the thigh above the aneurism, a tourniquet, Esmarch tubing, compressor or digital pressure being added and the apparatus kept in place for an hour or two hours completely cutting off the arterial flow. Great care was taken not to compress the aneurism. This does not appear to have been on account of possible danger from the compression, but on the theory that pressure would cause the clot to be smaller than the calibre of the sac and hence liable to be broken up when the blood stream began to flow against it. The success reported was variable, about one-half of the cases being cured. Two deaths occurred, one of which was not fairly attributable to the method pursued. In the cases of failure the patients seem to have been no worse than before the operation, and the performance of other operative measures was not precluded.

The two cases I have reported will be seen to differ radically in method and *rationale* from any of these, the chief point of difference lying in the application of the bandage to the aneurism itself. Dr. Nash completely empties the aneurism by pressure of the bandage, keeps it empty for a considerable time by the use of the Esmarch tubing, then lets on a full stream to fill the sac suddenly and arrests it, the explanation being that the blood rushing into the empty, flaccid sac, and stopping short will form a rapid and firm clot.

But my case differs essentially from his in method, and, I think, will be found to involve a quite different principle. I applied the full force of a Martin's elastic bandage over the aneurism, with the intention of squeezing out its contents, but I am confident that I did not succeed in this, for after the application of the bandage the tumor seemed scarcely at all lessened in size or altered in shape. The bandage remained in place only five minutes, no tourniquet was applied, the femoral artery was stopped by digital pressure not longer than fifteen minutes, after which time the full force of the arterial stream produced no pulsation, the tumor being hard and quiet. The shot-bag pressure was an intermittent one, and at its best only slowed the circulation slightly. I must therefore conclude that the actual pressure of the bandage upon the aneurism produced immediately a firm coagulation of its contents. If I am right in this conclusion, it is evident that the cure of popliteal aneurism by the elastic bandage becomes a much simpler matter than by the method hitherto pursued. Of course there may be danger of rupturing the aneurismal sac by too powerful pressure, but I do not think this danger will be very great if we proceed slowly with an ordinary elastic bandage, not attempting to empty the sac, but merely to compress it very firmly and evenly over its whole extent. Also by not maintaining the pressure of the bandage for a long time, and by doing away with the prolonged use of a tourniquet we greatly lessen the other dangers, congestion of internal organs from forcing back the blood from the limb for a considerable time, and œdema, and possibly gangrene, of the limb as a result of the continued use of the apparatus. I admit the weakness of reasoning from one case, but the gratifying result of this one, and the freedom from suffering on the part of the patient, will, I hope, induce those who have the opportunity, to give this method a trial.

HYSTERO-EPILEPSY IN A BOY TEN YEARS OF AGE.

By E. J. KEMPF, M.D.,
OF FERDINAND, INDIANA.

As hystero-epilepsy is an affection confined to adult or menstruating females, rarely occurring in females before puberty and after the menopause, and in males, it may not be without interest to report a case in a boy ten years of age, that lately came under my observation. I will endeavor to give an accurate and faithful description of the case, and venture a few remarks.

Mr. Peter G., the father of the boy, is of a strumous diathesis. Several of his brothers and sisters have died of phthisis, and he, though still free of any local manifestations of this diathesis, is weak and sickly. His wife comes from a healthy family, but is of a nervous and hysterical temperament. The patient, Frank G., is ten years old, and much too large for his age and correspondingly slim. His body was never strong, and is very much inclined to sickness—the image of his father in this respect. His mental qualities and his nervous system are like his mother's.

The boy has always been noted for his peevish and nervous disposition and his cowardice. His eyes were always restless and extremely watchful of everything. He would tell cunning lies to attain a certain end, and was noted for his hypocrisy. For these reasons he was never liked by his teachers or his comrades. At home, he was petted by both parents, as he was the first-born child and the only son. Such is the previous history.

Dr. Paul Kempf, the family physician, gives the following history:

January 2, 1883, I was called to see Frank G., ten years of age, who complained of an inability to walk, stand, or sit, and of slight pains in the limbs. Temperature and pulse are normal, bowels are constipated, no appetite, face is pale, and the body seems to be ill-nourished. Typhoid fever being prevalent at the time, I thought the symptoms to be prodromic of this disease. At my next visit, I found the patient in the same condition; no better, and no worse. Pressure along the spine, and in fact pressure anywhere, caused flinching and pain. In a few days, palpitation of the heart and noises in the ear appeared. The other symptoms remained the same, the pulse ranging from 70 to 80, and the temperature from 99° to 100° F. I gave him purgatives, and iron and quinine. But as the patient did not improve, and as I suspected some spinal trouble, I requested a consultation with Dr. W. R. McMahan. He coincided with my views, and gave it as his opinion that the case was one of commencing caries of the spine in the cervico dorsal region, the pain along the spine being sympathetic.

The treatment of iron and quinine was continued, with the addition of Horsford's Acid Phosphate. The bowels were continually constipated, and at one of my visits I removed a large quantity of hardened fecal matter from the rectum. After this, I ordered daily enemata of warm soapsuds, to prevent a re-accumulation of the feces.

About three weeks after the commencement of the sickness the patient began to constantly moan in a peculiar monotonous manner at all times except during sleep. The disease seemed to have changed its character, or was becoming more fully developed. Spasmodic contractions of the muscles of the abdomen also were noticed. A few days afterwards hallucinations and delirium set in, followed by convulsions, frothing at the mouth, peculiar cries, and tonic and clonic contractions of all the muscles. The convulsions with frothing at the mouth would first appear, to be followed by tonic contractions of the muscles of the arm, forearm, and face, and clonic contractions, in the form of opisthotonos, would close the performance. The whole attack would last twenty or thirty minutes. The patient was seemingly unconscious during the attack, but would often remark at the end: "Now I am done." From five to a dozen of these attacks would occur during the day, the patient being entirely free of them during the night. The presence of the clergyman or myself would restrain the patient from having an attack. For other and sympathizing visitors he would often, as if to accommodate them, go through with the whole performance.

By the request of Dr. Paul Kempf, I was at this time called in consultation, and I will give the further description of the case. I found the patient in bed seemingly perfectly helpless. His eyes had a peculiar glistening look, and were intensely restless. No motion, sign, or gesture of any person in the room escaped his attention. He would continually moan in a peculiar monotonous manner, stopping whenever remarks were made by some one present. If these remarks were concerning him, or if questions were put to him, he seemed for a short interval to forget to moan, but immediately noticing the omission he would recommence. The moaning seemed to be a part of the boy's make-up. On turning the patient around to try the effect of pressure along the spine, I noticed that the patient said, "it hurts," before I even touched him. On touching him either lightly or roughly over the spine or any part of the body the remark, "it hurts," was repeated. Lungs, heart, liver, spleen, stomach, and abdomen—except a slight tympanites—were normal. The body seemed tolerably well nourished, though the boy's appetite was almost nothing.

During an attack the limbs and the body become rigid, the hands and wrists twist in all shapes, and the muscles of the face are distorted. This is followed by clonic spasms, the body being opisthotonically arched, the head being thrown violently backwards and the body was violently thrown alternately on to the occiput and the heels. This stage lasted five or ten minutes. The parents and attendants would try to restrain and straighten the patient during these contractions, but their efforts being futile, they at last only endeavored to prevent the patient from hurting himself by falling off the bed, by twisting his neck, etc. Weights had also been applied to both limbs to restrain the spasmodic contractions.

We agreed that the patient was suffering from hysteria, complicated with epileptiform attacks. The patient was given the following:

℞.—Ammonium Bromide, . . ʒij.
Sodium Bromide, . . . ʒij.
Elixir Valerianate Ammonia, . f℥viij.—M.
Sig.—A tablespoonful four times a day.

The other treatment, tonics and enemata, as well as the milk diet were continued. The parents were enjoined not to sympathize in the least with the patient. All unnecessary and sympathizing visitors were to be kept out of the room. During the attacks the patient was to be severely let alone. He was to sit up in bed propped up with pillows, and gradually to be persuaded to sit up in a rocking-chair. Three days afterwards we again saw the case. He was sitting up in a rocking-chair, and for the first time for weeks was not moaning. He had only two slight attacks on the fourth day after commencing with the bromides. The treatment was continued, and instead of the enemata, the following was prescribed to regulate the bowels:

℞.—Syrup Lacto-phosphate of Lime, f℥ijss.
Soda Phosphate, . . . ʒj.—M.
Sig.—Two teaspoonfuls as required.

Within two weeks the patients was convalescent and able to walk about. He walks in a peculiar stoop-shouldered sneaking way, complains of occasional pains in the limbs, and often pretends pains, aches, and lameness. He therefore still needs watching and treatment. The mixture of the bromides will be given him for several months and repeated in the future whenever thought to be indicated.

The parents are instructed not to sympathize with any of the boy's suspicious complaints, and always to suspect him.

Comments.—Hystero-epilepsy is a disease affecting females of a hysterical type. It is a condition in which paroxysms occur, characterized by great intensity of the convulsive phenomena, combined with more or less marked features which recall the phenomena of epilepsy. The symptoms vary in different cases. The disease occurs generally in females during the menstruating period. Some cases were prostitutes, others had suffered extreme fright, and others had been victims of domestic tragedies. Cases are on record in which epilepsy was the first disease, hysteria being added after puberty. Other cases had hysterical aura first, soon followed by attacks of epilepsy. Although the disease is one of the menstruating female sex, cases have occurred before puberty and after the menopause. A case has been reported by M. Parisot (*Journ. de Méd. de Paris*, and THE MEDICAL NEWS, September 30, 1882) as occuring in a young man eighteen years of age.

The case herewith reported resembles what is termed hystero-epilepsy in the female. The hysterical aura preceding the epileptoid attacks for several weeks, consisted of pains in the limbs, back, neck, and other parts of the body; palpitation of the heart; the peculiar moaning; noises in the ear, hallucinations, and the contractions of the muscles of the abdomen. After three weeks followed the attacks of delirium and convulsions; of tonic contractions and distortions of the muscles of the face and limbs, accompanied by cries and frothing at the mouth, and lastly came the opisthotonic movements, or the clonic contractions. During the attacks, the patient was seemingly unconscious, though this condition may be termed "perverted or altered consciousness" (C. K. Mills, *Journal of Mental and Nervous Diseases*).

The most remarkable feature of the case is its rapid cure, the treatment being the bromides and moral force. But of course a return of the disease is probable at any time, and, knowing this, the patient will be strictly watched, and treated as soon as any symptoms of hysteria reappear.

MEDICAL PROGRESS.

The Treatment of Severe Catarrhal Cystitis by Cystotomy.—Dr. Horovitz, of Vienna (*Wiener med. Wochensch.*, Nos. 13 and 14), remarks on the changes that have taken place in respect to operations on the bladder. At one time lithotomy was the only operation for the removal of stone or foreign bodies from the bladder. Lithotrity has, to a great extent, replaced it in these cases, and cystotomy is now widening the range of its applicability. He then describes cases of cystitis, which resist all treatment, whether medicinal or instrumental, and which, unless boldly taken in hand, lead on to fatal nephritis and pyelitis.

The urine in these cases varies in color, from light yellow to dark red-brown, is alkaline in reaction, with ammoniacal or fetid smell, of high specific gravity, with thick slimy deposit of mucus, pus, blood-corpuscles, epithelial cells, with crystals of triple phosphates and urate of ammonia, and large quantities of bacteria. In cases in which the kidneys are already involved, casts are to be found. The patient suffers extremely from great pain over the bladder and along the penis, from constant straining and consequent loss of sleep, and all catheterization is attended with great agony. His health is completely destroyed, by loss of sleep and appetite, by constant drain of albumen, and the accompanying febrility. The author maintains that a bladder in this condition (cystitis of the third degree, according to Dittel), resembles and must be treated like an abscess cavity, which discharges by a long and tortuous sinus, and is constantly bathed by an irritating and decomposed secretion. The urethra, even if healthy, is insufficient for the discharge of the thickened secretion, and this imperfect drainage necessarily aggravates the diseased walls of the bladder. There is also generally a loss of contractile power of the bladder, and not unfrequently a sacculated condition of that viscus, both of which also tend to retention of the secretion. In such cases, the only operation likely to be of any benefit is perineal section with free drainage.

In 1803 Bouchardat, and in 1855 Fergusson, performed cystotomy for relief of cystitis, but these cases were not published.

In 1867 Parker, of America, published an account of a case which he treated in this way in 1851.

The following is a list of all the cases published up to now:

	Cured.	Benefited.	Uncured.	Died.
Weir collected 47 cases.	23	7	4	13
Post published 1 "	1	..	..	..
Brass " 1 "	..	..	..	1
Verneuil " 2 "	1	..	..	1
Harrison " 2 "	1	..	..	..
Thompson " 2 "	2	..	..	..
Dittel " 3 "	2	..	..	1
Total, . 58	30	7	4	16

Thus of 58 cases, 30, or rather more than fifty per cent., were cured, while 16, or thirty per cent., died; of these, however, 15 suffered from deep-seated kidney mischief, which in all probability existed before the operation—that is to say, the operation was performed too late. The author insists on the necessity of careful examination of the kidneys by palpation, percussion, and analysis of the urine before deciding on an operation.

In 34 cases, lateral section was performed; in 5, bilateral section; in 10, median section; in 5, urethrotomy; in 2, prerectal section. Sir H. Thompson and Prof. von Dittel both consider that external urethrotomy affords quite sufficient drainage, and is less liable to secondary hemorrhage. The author considers that the condition termed by the English "irritable bladder" is not a fit case for the operation, as the symptoms depend not on an abnormal condition of the bladder, but on some disease of the kidney or urethra.

He finally describes five cases of Dittel's, of which two recovered and three died.—*London Medical Record*, June 15, 1883.

Pathogenesis of, and Nervous Accidents in Diabetes.—Dr. F. Dreyfous has recently issued a pamphlet on this subject, in which, among the numerous theories, he has selected five which he places at the head of the list, and discusses in turn: 1. The gastro-intestinal theory (Bouchardat); 2, hepatic (Cl. Bernard); 3, nervous; 4, pancreatic; and 5, that theory which attributes it to nutritive trouble. This last theory has been revived by the works of Prof. Bouchard. M. Dreyfous considers diabetes as a disease acting on all the tissues. It may specially affect a particular organ, but he is averse to attributing diabetes to a lesion of a single organ; as a general disease, it must have a general cause. He therefore regards the theory of nutritive troubles, as expounded by Bouchard, as offering the best explanation of its etiology.—*Archives Gén. de Méd.*, June, 1883.

Pupil Phenomenon in Certain Pathological Conditions of Infancy.—Dr. J. Parrot has noticed that, in several children affected with acute diseases of the brain or its membranes, while they were in a comatose condition, if he pinched the skin of the epigastrium sharply, the pupil suddenly and decidedly widened, sometimes to a size thrice that of what it originally stood at, and he argues that while the general sensibility is lost, the sensibility of the skin may remain. He explains the phenomena on the supposition that it is reflex through anæmia, in consequence of the skin irritation, resembling the mydriasis resulting from a deep inspiration. The cases he relates are as follows: Six of tubercular meningitis (three with, three without, post-mortem demonstration), four of hemorrhage into the pia mater (two with post-mortem), three of hydrocephalus, and two in which no cerebral lesions were found. He relates seven cases of various diseases other than of the brain, where, during the state of insensibility preceding death, he was unable to elicit the phenomenon. The writer gives the following conclusion: "A child, with or without convulsions, which is in a state of coma, and whose pupils do not react on sharply pinching the epigastrium, is neither affected with tubercular meningitis nor with hemorrhage into the pia mater. It is in an advanced state of asphyxia, and its death is imminent."—*Edinburgh Med. Journ.*, July, 1883.

Simple Means of Obtaining Local Anæsthesia.—Dr. Cheize reports a case in which, wishing to remove an ingrowing toe-nail, and being without a spray producer, he covered the toe with a pledget the size of a crown piece, poured ether on it, and evaporated this by means of a pair of bellows; in five minutes anæsthesia was complete and lasted while the nail was removed, and the matrix seared with the actual cautery.—*Glasgow Med. Journ.*, July, 1883.

Addison's Disease and the Suprarenal Capsules.—From a study of the literature bearing upon this subject, Dr. Carl Burger arrives at the following conclusions: The suprarenal capsules are, from their structure, to be classed among the blood-vascular glands, and have no important vital function to perform. They stand in no causal relation to the bronzing of the skin. This dark coloring of the skin occurs not only in Addison's disease, but may accompany a variety of cachexiæ. Disease of the suprarenal capsules is not infrequent, and often runs its course without any of the recognized symptoms of Addison's disease. The greatest variety of lesions of the capsules may be seen in different cases of Addison's disease. Addison's disease depends upon an affection of the semilunar ganglia and of the solar plexus. This affection is usually caused by some disease of the suprarenal capsules, most frequently a tuberculous inflammation. Disease of the semilunar ganglia and solar plexus may arise from lesions of other organs than the suprarenal capsules, or may even be idiopathic. The symptoms of Addison's disease may thus be present without any lesion of the suprarenal capsules.—*Practitioner*, July, 1883.

Means of Provoking the Secretion of Milk.—When the milk-secretion is slow in appearing in a lying-in woman, or when it ceases from mental or moral causes, it may be made to return by cataplasms or fomentations of castor leaves applied to the breast, or by suction of the nipple, or by means of electricity. The mammary gland is slightly compressed between two sponge electrodes, and a feeble current passed through the gland for ten or fifteen minutes. This may be done twice a day. After the first few electrizations, the breasts swell, the large veins appear on the gland and the milk secretion is set up.—*L'Union Méd.*, July 5, 1883.

Diarrhœa in Infants.—Dr. Jules Simon, among other forms of diarrhœa, alludes to the cerebral, and says: "Diarrhœa may assume a cerebral form, that is, it may be accompanied by certain cerebral phenomena or by eclamptic convulsions, even although the diarrhœa may be but slight. As a result of a profuse drain, a comatose condition may be developed. Again, meningeal symptoms may develop and meningitis be simulated." Many of the reported cases of meningitis with recovery are, the writer thinks, only cases with meningitic symptoms. The various forms of diarrhœa are discussed in detail. For the treatment of cholera infantum, the writer recommends (1) preventive measures to be adopted during the premonitory catarrhal stage, and (2) after the full development of the affection, alcohol internally and externally, and mustard baths.—*Edinburgh Med. Journ.*, July, 1883.

Hæmatoma of Pancreas.—At the meeting of the German Medical Society in Prague, on March 9, Prof. Gussenbauer showed a patient in whom he had punctured a blood-tumor of the pancreas (*Wiener medicinische Wochen.*, No. 13). The man was forty years of age, and had in the previous year become the subject of an acute "gastricismus," said to be caused by a monster meal, of which sausages, beer, and spirits formed the staple portion. Since that time he had been the victim of gastric and intestinal disorder, and his complexion had changed to a yellowish-gray tint. When first examined by Gussenbauer, a fluctuating swelling was detected between the navel and the xiphoid cartilage, apparently retro-peritoneal, and of about the size of two fists. The diagnosis rested, therefore, between soft sarcoma, abscess, and cyst, including hæmatoma. The duration of the affection (about three months) was held to be against the possibility of sarcoma. The absence of pain and the fixation of the tumor were regarded as opposed to the diagnosis of abscess. The diagnosis, therefore, lay, according to Gussenbauer, between cyst and hæmatoma either of the pancreas or suprarenals. Why the idea of hæmatoma should have suggested itself to Gussenbauer does not appear. It is curious that he should have mentioned it in arriving at a diagnosis by the process of exclusion. The probability is that his knowledge of the subsequent course of the case colored these preliminary remarks on differential diagnosis. A median incision was made through the abdominal wall directly over the tumor. The parietal lamina of the peritoneum was in process of being stitched to the anterior wall of the tumor, when an accidental puncture of the swelling permitted the escape of a dark-colored fluid. By means of a trocar, 1900 cubic centimetres of the fluid contents were drawn off. The wall of the cyst was in many places smooth; in others, especially beneath the transverse colon, rough and irregular. After the cavity of the cyst had been washed out, antiseptic dressings were applied. For the first days, a sanguinolent fluid with some black lumps escaped. The fluid discharged was proved to contain blood. No fever followed the operation. After a few days, an eczematous condition was observed about the wound, such as is met with in cases of gastric fistula. Some of the discharge was collected, and found by experiment to digest albumen (forming tyrosin and leucin), and to transform starch into sugar. Prof. Gussenbauer said that the fistula had twice spontaneously ceased to discharge, but the appearance of fever necessitated the restoration of the fistula, after which the fever subsided. Examination still revealed, at the time the patient was shown, the presence of a cavity about an inch long, and rather more than an inch wide, from which the pancreatic secretion yet flowed. The conclusion at which Gussenbauer arrived was that a cyst had formed in the pancreas as the result of obstruction in the duct. This was most probably produced by the presence of a stone, the existence of which might also explain the occurrence of hemorrhage into the cyst. No mention is made of the actual detection of a calculus. The stools were not characterized by the presence of fat, and the patient presented no signs of disease beyond what have been mentioned. Prof. Chiari, in the course of some remarks on the origin of cysts in the pancreas, mentioned a case in which, as a result of "peripancreatitis," the whole of the pancreas had necrosed, and had been passed per anum. There was no doubt about the sequestrum being pancreas. The man recovered.—*Medical Times and Gazette*, June 30, 1883.

Resection of the Knee.—Until recently, M. Ollier has been an earnest opponent of this operation. Lately, however, he has completely retracted everything which he has said against it, and comes out as an earnest advocate for it. He has not altered his opinion of its value in young children. His investigations and those of Prof. Humphry show that if the whole of the lower epiphysis of the femur be removed, as is often necessary, the growth of the limb is interfered with to a disastrous extent; and if the surgeon be able to preserve a part of the epiphysis, yet the disturbance occasioned by the operation to the nutrition of the actively growing portion that is left behind is so great that even then the limb is seriously shortened. On this account M. Ollier rejects altogether the operation of excision of the knee for patients under eight years of age. He further adds, in reference to this, that these patients are excellent subjects for incisions into joints, scraping, and free drainage; and that, if these measures fail, amputation is the sole resource. In this view we believe he is in accord with British surgeons.

The change that has taken place in M. Ollier's estimate of the value of excision of the knee has resulted from the success attending in his hands the use of a strictly antiseptic plan of treatment.

The method of operating that he advocates is the subperiosteal, but he would vary its details according to whether it is performed for injury or disease. For injury he recommends a single vertical median incision over the front of the joint, extending quite into the joint above the patella, and also below where the ligamentum patellæ is to be split. He then saws through the patella vertically, but before completing the excision of the articulated surfaces through the opening thus made, he makes an incision for drainage on each side into the joint, one just in front of the biceps tendon, the other in front or behind the sartorius, and subsequently he places a drain in each of them. He then divides the crucial ligaments, bends the joint fully, protrudes the femur and peels off from it the periosteum and ligamentous and tendinous attachments, and saws off the end. He treats the tibia in the same way. The sections of the patella are then wired together, and the wound closed with a drain at its upper and lower end. When operating for disease he recommends that a freer opening be made into the joint, as more room is required for the following up of all the recesses of the synovial cavity and for the treatment of the patella itself. He therefore employs an **H** incision, making a straight cut into the joint below the patella, extending laterally not quite as far as the lateral ligament, and not being quite so long as the transverse diameter of the condyles. From each extremity of this he makes a vertical cut upwards and downwards, of a length varying with the extent of the disease and the amount of bone requiring removal. In this way two small flaps are marked out, of which the lower is always the smaller. Two incisions for drainage are made at the sides of the joint, as in the other operation, care being taken to have the inner one behind the sartorius tendon, and both of them made without injury to tendons. The upper flap is then raised, the joint well explored, and the patella, if necessary, removed by shelling it out from its anterior periosteal investment. The periosteum and ligamentous and capsuled attachments are then carefully peeled off from those parts of the femur and tibia which are to be removed, and those bones are sawn across. The synovial membrane is excised or scraped, as the case may be, and an opening for drainage made at the top of the suprapatellar pouch; then the bones are united by two wire sutures, and the cutaneous incision united, special care being taken to stitch together the cut ends of the ligamentum patellæ.

M. Ollier first points out that the aim of the surgeon is to obtain bony union after excision of the knee. To preserve the periosteum, where possible, directly aids in the ossific union of the two bones, while to leave the lateral ligaments as well as the posterior intact, is an important aid in maintaining the bony parts in exact and firm apposition. He lays considerable stress upon the importance of suturing carefully the divided ends of the ligamentum patellæ, so as to enable the quadriceps extensor muscle to counteract the tendency of the flexors to displace the tibia backwards. In cases of compound comminuted fracture into the knee-joint, M. Ollier is in favor of excision, even where a great length of bone has to be removed, and he suggests that in such cases it would be well to remove a part of the soft tissues in front of the joint; if not, when the ends of the bones are approximated the soft parts are greatly relaxed and bulge considerably around the bone, and as the flexors shorten more quickly than the extensor muscles, there is great danger of displacement of the tibia backwards, which can be prevented by artificially shortening the extensor tendon.—*Lancet*, June 30, 1883.

Influence Exerted by the Treatment of One Ear upon the Other Ear.—Eitelberg thus formulates his conclusions upon this subject:

1. In many cases the treatment of one ear causes an improvement in the hearing power of the other ear, which has not been treated, while a diminution of the hearing power is very rarely produced.

2. The greatest difference in favor of the improvement of hearing in the ear not treated occurred in cases of one-sided acute or chronic otitis media purulenta, with defective hearing in the other side.

3. In disease of both ears, when only one ear was treated, an improvement very often appeared in the other ear, not only in respect of the hearing power, but also in respect of the existing subjective noises.

4. In many cases an improvement, and even complete restoration, of the hearing power appeared in the ear not treated, not immediately upon the treatment of the other ear, but some time after.

5. In some cases, after a certain time had elapsed, the improvement in the hearing subsided and the ear returned to its former condition.—*New York Medical Journal*, July 14, 1883.

Treatment of Ulcer of the Stomach.—Dr. F. P. Atkinson reports a case of chronic gastric ulcer, which was quickly benefited by his treatment, though she had had no relief from any previous treatment. She had taken carbonate of iron, carbonate of soda with bismuth, prussic acid and calumba, bismuth, strychnine, and pepsin, effervescing citrate of potash with Schacht's solution of bismuth, and various sedatives, with a diet of beef-tea, mutton-broth, barley-water, milk and lime-water, but without there being any change in her general condition. The tenderness, the pain, and the vomiting continued unchanged, and when he was called in to see her she said she felt so weak that she was scarcely able to stand. She was exceedingly thin, and with the exception of a flush upon her cheeks, she had not a particle of color either in her face or lips, and her pulse was quick and thready.

Complete rest in bed was ordered. A teaspoonful of Brand's liquid essence of beef, or a teaspoonful of Valentin's meat juice in a little cold water, in small quantities every four hours; a wineglassful of milk and lime-water (mixed in equal proportions) to be taken frequently, and the body to be rubbed with olive oil morning and evening. The beef essence and milk were very gradually increased, and when the pain had almost subsided a little sponge cake, bread, barley-water, arrowroot, etc., were allowed, and at last, by very slow degrees, ordinary food replaced the liquid diet. Stimulants of all kinds were interdicted.

The medicinal treatment consisted of: 8 grains of tartrate of iron, 15 minims of tincture of conium, 15 minims of tincture of calumba, 15 minims of glycerine, in one ounce of water, three times daily.

No aperients were allowed. After a time the mixture was replaced by 15 minims of Bravais' dialyzed iron, three times a day. Since the last attack, about a year ago, the patient has very materially gained in flesh and color, and has been able to take ordinary diet, except for two or three days, and can walk four or five miles without fatigue.

After this she had another attack of vomiting, when liquor potassæ had to be given for a day or two first, and koumiss seemed to agree better than the milk and lime-water.—*Practitioner*, July, 1883.

Elongation of the External Nasal Nerve in the Treatment of Glaucoma.—A. Trousseau describes, in his inaugural thesis, a mode of treatment which seems well adapted to replace other operations for glaucoma, and which is likely to take high place in ocular surgery. This new method is due to M. Badal, of Bordeaux, who has seen its good results. Trousseau considers this new operation superior both to iridectomy and sclerotomy, and claims the following advantages for it: 1. It is a very simple operation, which can, in most cases, be substituted for iridectomy, and especially sclerotomy. 2. It succeeds in some cases in which these operations would fail. 3. It may often retard the more serious operations above mentioned, or even enucleation, and may prevent their being employed. 4. It is always more acceptable to the patients, and can always be tried without inconvenience, since in case of failure, operations on the eyeball may be resorted to. 5. It should be performed in the prodromal stages of glaucoma. 6. It promptly calms the pains of glaucoma, and often prevents a return. 7. It sometimes restores acuity of vision. 8. It abates intra-ocular tension. 9. In case of failure from elongation of the external nasal nerve, it may be well to perform a similar operation on other sensitive nerves of the orbit.—*L'Union Méd.*, June 7, 1883.

Morbid Changes of the Throat, Larynx, and Air-passages in some Acute Infectious Diseases.—Dr. E. Löri, of Budapest, gives the following as some of the changes which may be observed. In measles, twelve to thirty-six hours before the appearance of the skin rash, there is a diffuse or macular hyperæmia of the mucous membrane of the throat, larynx, and air-passages, diffuse usually in the mouth, macular on the tonsils and back of the throat. Within twelve hours from the appearance of this hyperæmia there occur small papules, first on the palato-glossal folds. About the time that the skin eruption appears there is profuse catarrh of pharynx, larynx, and trachea, with rapid shedding of epithelium, and frequent formation of superficial erosions. In the trachea the swelling around these latter may give rise to stenosis. According to the writer, the appearance of such ulcers in the larynx augurs the occurrence of tuberculosis. In scarlatina, the throat is affected twelve to thirty-six hours before the outbreak of the eruption. The writer states that there is often a sudden disappearance of the affection of the mouth and pharynx coincident with the eruption on the skin coming out. Frequently the eruption in the mouth closely resembles that found with measles. In rubeola there is also hyperæmia, diffuse or spotted, of the larynx and trachea. In smallpox the mouth is affected at the same time as the skin. The pustules are small and imperfectly filled, dry up in two or three days, and in six days are only represented by red spots. Bleeding from them is very common. The writer recommends the use of ice poultices round the neck, ice internally, and such astringents as tannin applied after puncture of the pustules. In chickenpox there occurs either diffuse hyperæmia of the mucous membrane, or a few scattered pustules. In typhus and typhoid, acute catarrh of the pharynx, larynx, and trachea is of frequent occurrence, and often proceeds in the larynx to the formation of ulcers, which have little tendency to heal, and occasionally, about the sixth or eighth week of the disease, cause perichondritis. For this latter condition, "when diagnosed with certainty," the writer recommends tracheotomy as early as possible. In whooping-cough there is usually some catarrh of larynx and trachea, and bleeding from the mucous membrane is frequent. The appearance, during the course of whooping-cough, of ulcers in the larynx, the writer regards as very suspicious of the onset of phthisis. —*Edinburgh Med. Journ.*, July, 1883.

Treatment of Tinea Capitis.—1. The group of diseases (*Herpes tonsurans*, *Porrigo favosa*, and *Porrigo decalvans*) comprehended under this title, being recognized as parasitical dermatoses, their rational treatment must, of course, be directed against the parasites. Two modes of procedure fulfilling this condition have been found preferable:

a. Epilation, which exterminates the parasites by destroying the organic structure in which they make their habitation.

b. The local application of croton tiglium, which accomplishes the same object by inflaming, without destroying, the derma and hair follicles, and thus removing the infested hairs.

2. In cases not too inveterate, a cure or decided amelioration is usually obtained within a period varying from three to eight months, and after from three to five applications of the remedy.

3. Clinical experience has shown that this treatment is not followed by any special tendency to relapse.

4. As to the other unfavorable results which have been charged to the employment of this remedy, viz., intense folliculitis, inflammation of the scalp and even the occipito-frontal aponeurosis, and erysipelas, it is precisely these evils which the croton-oil dressing, in the form recommended, is intended to avert. Neither the above symptoms, nor the alopecia which has been said to follow them, have been produced in any of our cases.

5. The only unpleasant consequences we have ever witnessed have occurred from the accidental transfer of the ointment to other surfaces, such as the conjunctiva, in which latter case a conjunctivitis might possibly arise; but this danger is easily obviated by protecting the scalp with a properly adjusted cap. We have never known such an accident to result in anything more serious than a slight conjunctival hyperæmia.

6. As to erysipelas, statistics show that it follows the croton treatment in an average of four cases out of a thousand, and that it has invariably been cured.

These risks are insignificant when measured against the extreme pain which epilation inflicts upon a child, and when also the insufficiency of the latter method is considered, since the hairs almost always break off under the operation.

7. To sum up our subject, the results of treatment by croton tiglium dressing may be pronounced highly satisfactory in *Herpes tonsurans*, and encouraging in *Porrigo favosa*, and in certain cases of *Porrigo decalvans*.—*Journ. of Cutan. and Vener. Diseases*, July, 1883.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,
Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in registered letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, JULY 28, 1883.

CHOLERA PROSPECTS.

Epidemic cholera has made a long stride towards Europe and this country by establishing itself in Egypt, where it is now prevailing in a severe form.

There is no doubt of its existence in Cairo, and probably it has reached Alexandria, although no definite intelligence on this point has yet been received. There are rumors of cases in Malta and Trieste, but these are improbable.

The governments of Western Europe have become alarmed; extra quarantine precautions are insisted on; the Spanish Cortes has voted a million of pesetas to meet the cost of preventive measures, and even the Local Government Board of England has issued a memorandum of warning, directing measures of precaution against the introduction of the disease.

Cholera has also been increasing in India. During the year 1882, 2,240 deaths from cholera were reported in Calcutta, being more than in any year since 1869, and thus far the number of deaths this year from this cause has exceeded that of 1882.

It is possible that European governments, which seem fully alive to the danger, and have had timely warning, may be able to check the disease; but if we take the history of preceding epidemics as a guide for prophecy, the check will be only temporary. It will not be surprising if the disease does not appear in Europe for several months, and in the mean time gradually die out in Egypt. Should this be the course of events, the present panic and spasm of sanitary activity which it has produced will subside; commercial interests will again come to the front; merchants and shipowners will be vociferous in their protests against the uselessness of quarantine: vigilance will relax, and the next thing will be rumors of cholera in European ports.

The danger to this country is comparatively small until the disease reaches Europe. It has usually, if not always, come to us by the lines of emigration from the north of Europe—from Hamburg and Southampton.

It is no guarantee against the presence of the cause of cholera in a ship that the disease did not prevail in the port of departure at the time of sailing, or that no cases have occurred on the vessel during the voyage, for it is sufficiently probable that the cause of the disease has been carried far into the country by the baggage of emigrants who showed no signs of the affection until this baggage was unpacked, to make it prudent to insist on thorough exposure and disinfection of all such material where there is any ground for suspicion that cholera may have existed in the vicinity from which the emigrants come.

It must be remembered also that the precautions taken at Canadian ports are nearly as important for our protection as those of our own.

But supposing the disease is introduced, say next spring—and there are at least three chances out of five that it will not reach us before that time, while it is about an even chance that we may have it within a year—are we prepared for it?

Remembering that the probabilities are that this is a question of local cleanliness and freedom from pollution of water-supply, we fear that the answer for many cities must be, Certainly not.

The cities where excreta are stored in cesspools and privy-vaults, where the sewers are badly constructed, foul, leaky, and in places little more than elongated cesspools, where the soil has become gradually saturated with organic matter, and where wells are used by the people because the water is cool and sparkling, even though a general water-supply has been introduced, and the cities whose general water-supply is taken from a stream into which, ten or twenty miles higher up, is discharged the sewage of a village or town—all these are in danger, and must do something more than scrape their streets and alleys, and scatter a little lime over the worst places, if they would have an insurance against an epidemic of cholera which is of real value.

THE SURGICAL TREATMENT OF EMPYEMA.

Osler, Fenger, and Jas. C. Wilson have each contributed to our columns, lately, extremely interesting and instructive lectures or papers on empyema and its treatment, which naturally renew our interest in the subject. The topic is old—for pleurisies with effusion doubtless have always existed—but there are few subjects indeed as to which it does no good to review our knowledge from time to time, to seek warning from our errors, encouragement from our improvements and successes, and from both to gain incentives to closer observation, deeper research, and further triumphs.

When the aspirator was first invented many jumped at once to the conclusion that this gave us the whip-hand of all such accumulations. For absolute certainty of diagnosis the aspirator is essential. It is demonstrative. But, in passing, let us add that it is often forgotten that we have always at hand a simple, effectual, and cheap aspirator in the hypodermic syringe, which for diagnostic purposes is equally efficacious.

But, while extremely useful and often curative in children and in cases of serous or sero-fibrinous effusions, it was soon found that in adults, and especially if the fluid were purulent, repeated aspiration would not cure, but give only a temporary relief. What was wanted was not only a safe, speedy, and thorough evacuation of the pus, but its *continuously* thorough evacuation. That is to say, as in the case of any other purulent accumulation, *e. g.*, an abscess, so in purulent accumulation in the chest the same rule holds true—free exit. Different methods of reaching this result have been advocated by various practitioners. One uses a permanent canula, another a drainage-tube, a third free incisions, a fourth even resects a rib. With each of these methods we may use or modify, or discard antiseptic precautions. With each we may use injections to wash out the cavity, or not, as is judged best. Whatever modifications of details are adopted, free escape for the pus is the cardinal point to be secured, and if we can prevent decomposition of the pus, so much the better. *Il y a fagots et fagots.* So too there is pus and pus—some sweet and healthy, and some ill-smelling and decomposing. In all the latter cases certainly, and as a rule even in those in which the pus is sweet, washing out the chest with disinfectants, permanganate of potash, iodine, corrosive sublimate, etc., is clearly indicated. Carbolic acid should not be used, for the dangers of its absorption with poisonous symptoms is an undeniable risk.

Resection of the ribs, except when so close to each other as to prevent free drainage, is not advisable. Especially is this true in the resilient chest of children. On the other hand, in old cases of empyema in which the lung is held fast by adhesions and the rigid chest-wall cannot fall in to meet it, the thoracoplastic operation of Estlander, in which several ribs are resected to allow the approximation of the two surfaces, is certainly demanded.

Paracentesis is not without its dangers. The trocar if heedlessly used may wound the lung; even the moral fear of the operation or the pain attending it has produced fatal syncope, but this is so rare a possibility as to be practically disregarded, especially as both may be modified or avoided by soothing and gentle personal control of patients, and the use of local anæsthesia; too hasty withdrawal of the fluid, especially if done with forcible and uneven suction, as by a syringe, may injure the more or less firmly fastened lung and produce hemorrhage from the ruptured adhesions, or even rupture of the lung tissue with pneumothorax. To avoid injury to the lung, as well as to remove all the pus, Parker has even proposed to allow carbolized air to enter the chest by a hypodermic needle, but injections would effect both results better and avoid the dangers of pneumothorax.

But *per contra*, it is not to be forgotten that inaction has its dangers as well as action. A Fabian policy is not always the wisest. While attempting the absorption or elimination even of a serous fluid by purely medical means, sudden death may occur from acute œdema of the well lung; by hampering the heart's action if the effusion be very large in amount; by a kink in the great vessels, especially the vena cava, if the heart be greatly displaced; or by thrombosis of the pulmonary vessels or by syncope: and if these more immediate risks are escaped the remoter ones of exhaustion, septicæmia, and tuberculosis are none the less real, because deferred.

Pus is always an enemy, and must be got rid of as speedily as other indications make it wise to do it. Homén saved half of his 52 cases treated antiseptically. Fiedler has done thoracentesis 150 times in 112 patients, saving 21 in good health, 25 died or were dying with phthisis, while 66 who also had phthisis were cured so far as any return of the effusion was concerned.

PARALDEHYDE—A NEW HYPNOTIC.

Every addition to our resources in the direction of safe and efficient hypnotics is especially desirable. We owe to our Italian colleagues this new contribution. It may be desirable to put before our readers some exact information regarding the physical and chemical qualities of this substance, especially as it is likely to enact so important a *rôle* in the therapy of the future.

Paraldehyde is a polymeric modification of aldehyde. What is aldehyde? This is, in brief, alcohol deprived of its hydrogen, and although a generic term applied to a group, in this connection means acetic aldehyde. Paraldehyde being merely the same substance in respect to its atoms, but which are arranged differently, may be suspected to have analogous properties. Above the temperature of 51° F. it is a colorless liquid, having a peculiar odor, and a specific gravity of .998. It boils at or about 225° F., and it is soluble in 8 parts of water at 52° F. Aldehyde acted on by chlorine is converted into chloral. These chemical facts indicate the position of paraldehyde from the physiological standpoint, and probably suggested its utility as a hypnotic.

For medicinal administration, the dose ranges from ʒss to ʒijss, and it is said the best results are had from the maximum dose.

In the trials made of it, paraldehyde has proved to be an admirable hypnotic, possessing most of the qualities but none of the dangers of chloral. It acts first on the cerebral hemispheres, and causes torpor without the preliminary excitement so common in the action of the sleep-producing class. After the hemisphere, the action extends to the medulla oblongata, and then to the cord. A lethal dose suspends the functions of the medulla and the respiratory centre, and the action of the heart ceases after the respiration. In respect to the effect on the heart, paraldehyde is far safer than chloral; indeed, it appears to be free from the danger which renders the administration of chloral in large doses so doubtful an expedient. Its effect as a hypnotic is not so persistent as that of chloral, but it may be maintained by the repetition of sufficient doses. No ill-effects of any kind—no after-nausea, or depression, or headache—have been observed to follow its very free administration.

Paraldehyde may be prescribed as a hypnotic in the various conditions usually requiring such a remedy—in fevers, rheumatism, gout, prurigo, etc. (Morselli). It is, however, in mental and nervous disorders that it will probably be most used. By the Italians, Albertoni, Morselli, and others, it has been prescribed with very marked success in acute mania, in the wakefulness of dementia paralytica, in hysterical paroxysms, and in insomnia arising under ordinary conditions. They have found it especially useful in that form of wakefulness caused by the fear of inability to sleep. Surely, if these statements be confirmed, an important remedy has been discovered in paraldehyde.

THE ORGANIC BASES OF URINARY CALCULI.

Ebstein has recently called attention to the fact that all uric acid concretions, whether in the shape of sand, gravel, or stone, contain a framework of albuminous material which remains after the uric acid is completely dissolved out. The same is true of calculous formations of oxalates and phosphates.

We cannot determine from the brief abstract which Prof. Ebstein publishes in the *Deut. med. Wochenschr.* for May 16, whether he considers this a new fact, but we presume he does from the fact that he considers it worth while to announce it in advance of his forthcoming work on "Calculi." Be that as it may, Dr. H. Vandyke Carter, in his little book on *The Microscopic Structure and Formation of Urinary Calculi*, published in 1873, alludes to this organic basis or framework, which he speaks of as being finely granular and fibrous, as present in calculi made up of uric acid, urates, oxalate of lime, and phosphate of lime. He speaks of it as an essential part of these submorphous structures, and as especially distinct in calculi made up of urates and of phosphate of lime. The essential nature of this organic matrix was also foreshadowed by Prof. Rainey's paper, *On the Formation of Shells*, London, 1858; and Dr. W. M. Ord's paper, *On Molecular Coalescence, and on the Influence exercised by Colloids upon the forms of Inorganic Matter*, published in the *Quar. Journ. Mic. Sci.*, 1872.

Prof. Ebstein also claims to have discovered a certain relation not heretofore appreciated between the uric acid infarcts so common in the kidneys of new-born children and the general process of calculous formation. This is also promised in the forthcoming volume referred to.

THE SALTS OF LITHIA AS SOLVENTS OF URIC ACID CALCULI.

Garrod, who introduced the salts of lithia, for the purpose of alkalizing the blood and urine, has brought forward in his Lumleian lectures, now in course of publication, fresh evidence in support of his views. Of the alkalies now employed in medicine, lithia is the most powerful as an alkali *per se*. But Dr. Roberts, of Manchester, England, an authority in renal pathology, has called in question the solvent powers of lithia, over uric acid calculi, which Garrod had strongly affirmed. Roberts submitted experimental evidence in support of his position that the salts of potash had greater activity as solvents of uric acid concretions than lithia. Dr. Garrod has, however, in the lectures above referred to, clearly shown the fallacy in Dr. Roberts' experiments, and has demonstrated anew and conclusively his original postulate that lithia is the most powerful of the alkaline group in respect to its solvent action on uric acid. Several consequences follow this demonstration: If the problem consists in the use of an alkali to effect the solution of an uric acid calculus, say lodged in the pelvis of the kidney, the agent most certain to accomplish this, is a salt of lithia.

Again — if a remedy is required to increase the alkalinity of the blood, to effect the oxidation of uric acid, and to prevent the maladies due to an excess of this acid in the blood, lithia promises the best results. We have seen from the use of lithia, in that morbid complexus entitled lithæmia, the most conclusive evidence of its power to effect the oxidation and excretion of the offending substance. A very elegant mode of exhibiting lithia is to give the carbonate in effervescence. A granular effervescent salt is now largely used in England. The citrate in solution in water is the usual form of the remedy now prescribed in this country.

THE first number of the Journal of the American Medical Association, issued under the date of July 14th, has just come to hand. It is a double-column quarto-page journal, and contains the minutes of the late meeting of the Association, original articles on Tonsillotomy without Hemorrhage, by W. C. Jarvis, on the Treatment of Otorrhœa with Antiseptic Powders, by H. Gradle, and on the Restoration of a Lost Cheek, by a Flap from the Shoulder, by Edmund Andrews, M.D. Then follows a department of Medical Progress, an editorial on "The Change," and finally, departments of Correspondence and News Items complete the number.

Dr. N. S. Davis, when accepting the editorship, disarmed criticism by asking the Association not to expect too much of him in the first issues. It, therefore, only remains for us to express the pleasure it affords us to welcome the new journal, and cordially to wish it the fullest measure of success.

SOCIETY PROCEEDINGS.

AMERICAN OTOLOGICAL SOCIETY.

Sixteenth Annual Meeting, held in the Catskill Mountains, July 17, 1883.

(Specially reported for THE MEDICAL NEWS.)

THE American Otological Society held its Sixteenth Annual Meeting at the Hotel Kaaterskill, Catskill Mountains, N. Y., on Tuesday, July 17th.

The Society was called to order at 10.30 A. M. by the *Vice-President* DR. J. S. PROUT, of Brooklyn, N. Y.

Twenty-three members were present. Four new members were elected.

After the routine business the order of the bulletin was taken up, on which the titles of thirteen communications were presented.

DR. W. W. SEELY, of Cincinnati, Ohio, reported

A CASE OF PRIMARY EPITHELIOMA OF THE AURICLE; REMOVAL OF THE ENTIRE AURICLE BY THERMO-CAUTERY.

The case was that of a man, sixty years old, who had been bitten, while asleep on the right ear by a rat. The wound never healed, though treated in various ways, and presented at the time he was first seen by Dr. S., a large, sensitive, readily bleeding sore. It had developed rapidly during the last year, and bled at the slightest irritation, so that the man had an exhausted and anxious appearance. The original point of the wound was near the summit of the helix; at the time of Dr. S.'s first examination it involved a large portion of the auricle. The entire auricle, except the lobule was swollen and reddened; the skin behind the ear for some distance was reddened, but not infiltrated, the glands not enlarged. The entire auricle was removed by thermo-cautery (Paquelin's); slight hemorrhage; three or four small arteries spurting a little, till touched; the surface entirely covered with a thick layer of boracic acid. The suppuration was but slight and the patient sent home in less than five weeks with a perfectly smooth scar. The orifice of the meatus retained its normal calibre.

The author quoted a few cases which have been reported in the literature of otology, and from the small number of these cases, comes to the conclusion that primary epithelioma of the auricle is a *rare* disease, notwithstanding the English translation of Politzer would make it appear to be by no means rare. The specimen was presented with the paper.

DR. J. A. ANDREWS, of Stapleton, Staten Island, presented a paper on *The Intermittent Perception of Sound, as Conveyed through the Air and the Cranial Bones, with a Brief Summary of the Results of Treatment in Chronic Aural Affections, with Impaired Hearing*, which was read by title and referred to the Committee on Publication.

DR. J. A. ANDREWS also presented a paper on

THE RECOGNITION OF BRAIN COMPLICATIONS IN AURAL AFFECTIONS.

Five cases were detailed from his own experience, in which death occurred secondary to an aural affection. He called special attention to the importance of examining the eye in aural affections in which other symptoms, although obscure, excited suspicion of an intra-cranial complication. In all of his cases an ophthalmoscopic examination revealed papillitis. He considered the condition of the disk, either papillitis or a hazy, slightly œdematous appearance of the optic-nerve disk, a very valuable corroborative evidence of a cerebral complication, especially where the other symptoms were obscure. Dr. Andrews considered the character of the headache as an important symptom. He believed that it was more continuous, occurred less in paroxysms in abscess of the brain than the headache in brain tumor. Fever was very often absent, even in the terminal stage. From his own observations, the sight is most affected on the side of the cerebral lesion.

In connection with this subject, DR. S. SEXTON, of New York, presented a paper on *External and Internal Inflammation of the Mastoid, with Cases*, which was read by title and referred to the Publishing Committee.

DR. C. H. BURNETT, of Philadelphia, reported

A CASE OF MASTOID DISEASE; ARTIFICIAL PERFORATION OF THE BONE; TEMPORARY RELIEF; DEATH FROM PYÆMIA;

and DR. READ J. MCKAY, of Wilmington, Del., a case of

ACUTE DESQUAMATIVE INFLAMMATION OF THE EXTERNAL AUDITORY CANAL; ACUTE OTITIS MEDIA, MASTOIDITIS, AND CHRONIC MENINGITIS; RECOVERY.

Dr. Burnett in his paper showed that the purulent disease may not necessarily affect the brain in cases of mastoid disease, but may produce death by pyæmia of a chronic nature, affecting organs remote from the ear, as the lungs or the liver. Also, that the operation of trephining the bone is comparatively unattended with danger, and affords the one slim chance of death in cases of true intra-mastoid disease, which must necessarily furnish an embolic source, if the products of inflammation, *e. g.*, purulent and cheesy *débris*, are pent up in the mastoid cavity. For in such cases there are the chances of death from embolism, while none arise from the operation. In the case reported by Dr.

Burnett, the patient survived the mastoid operation two weeks; the wound nearly healed, when the man was seized with a chill, and rapidly sank from embolic hepatitis.

Dr. McKay's case occurred in a woman, 77 years old. She was delirious and extremely ill for months. She recovered under hypodermic injections of morphine and minute doses of calomel, with liberal use of stimulants and food.

The discussion on these different papers occupied a great part of the morning session, and was continued at the evening session.

Dr. Sexton exhibited a former patient, now a waiter at the hotel, who had been suffering from mastoid disease, in consequence of chronic suppurative otitis media complicated with ozæna. In this case a natural opening formed, the remnant of which still showed in a dent in the bone, and he had kept this open until the discharge ceased. For treatment he had only given calcium sulphide.

In a very large number of cases of aural diseases in general, and of the mastoid in particular, he found no occasion for trephining the mastoid. He relied especially upon the calcium sulphide. If this remedy has proven unsuccessful in the hands of some of the members, it was because too large doses had been given. The dose should never exceed one-tenth of a grain. Of late he does not apply leeches. He calls attention to the frequency of the pus burrowing through the posterior wall of the meatus and he tried to favor this process and removed sequestra as soon as possible. He does not consider pain so important in regard to indications for operative interference; there is other evidence needed. Moreover, the pain is not confined to the mastoid; oftener the side of the tympanic cavity is the seat of the pain, more than in any nerve distribution in the mastoid cells. He asked Dr. Knapp what value the ophthalmoscopic examination had in diseases of the mastoid with brain complication.

Dr. Knapp remarked that neuro-retinitis is not a frequent, but when present a most important, symptom, because it is objective, and is positive evidence that the inflammation has extended to the cranial cavity. It is not only of very great value in determining the appropriateness of opening the mastoid in many cases, but also in furnishing us a kind of barometer, whose rise and fall (that is, increase and decrease of the neuritis) will point toward aggravation or amelioration of the tympano-mastoiditis. He has found it of peculiar value at the period when the opening of the mastoid may be allowed to close, which should not be as long as the neuro-retinitis has not yet disappeared.

In cases where the indications for opening the mastoid were doubtful, he relied more than on any other symptom upon a *constant intense pain*, radiating from the ear and mastoid over the corresponding half of the head, sometimes being more pronounced at the vertex, at other times more in the forehead or the occiput.

From the drift the discussion had taken, it would almost appear as if there were no precise indications for the opening of the mastoid. He desired to state that he considers this operation as legitimate and in many cases as unambiguously indicated as any surgical operation, for instance that of glaucoma.

In *acute* otitis, he considers it indicated when the general and cerebral symptoms, in spite of rest and antiphlogosis, are constantly increasing, the pain extends over the whole half of the head, the mastoid is tender and puffy, and especially when together with the aggravation of these symptoms a stoppage or considerable diminution of the discharge points to retention of pus, the natural escape of which cannot be reëstablished by warm ear-baths, steaming, poulticing, etc.

In *chronic* otitis, he considers it indicated when symptoms on the external face of the mastoid, a scantiness or absence of discharge, more or less developed cerebral symptoms with periodic aggravations and the inefficiency of local non-operative treatment demonstrate that pus, cheesy material, or sequestra are retained in the mastoid cavity. If nature has made a perforation and the disease does not tend to a speedy recovery, this opening is to be regarded as insufficient, and should be enlarged with the chisel, whereupon the probe will determine the character of the contents of the mastoid cavity, and a sharp spoon, forceps, syringe, and a drainage-tube, will secure the recovery.

Dr. Gruening remarked that in the case shown by Dr. Sexton, it was not the sulphide of calcium, but nature, to which the recovery was due, and in order to be consistent with his theory, in place of keeping the opening made by nature open until the discharge had ceased, he should have endeavored to close that opening.

Dr. Holt had seen forty cases of mastoid disease with three deaths in two thousand cases, but had never trephined the mastoid.

Dr. Burnett quoted statistics from Schwartze's series of operations, to again point out the comparative freedom from danger in the operation.

Dr. Strawbridge had seen five thousand cases of purulent middle-ear disease, with about seventy cases of mastoid disease. Only one death occurred, in a child, forty-eight hours after the disease set in. Although he had thoroughly prepared himself for the operation by repeated operations on cadavers, he had never had a chance to do the operation on the living body, as he generally succeeded with poulticing and good food in relieving his cases. He believed the poulticing acted as a stimulant.

Dr. Bartlett said that in regard to the value of ophthalmoscopic examination he had often examined a case of melancholia, occurring in his own family, and found double optic neuritis very plainly marked; that as the case advanced the appearance of the optic disks returned to a nearly normal condition, when convulsions occurred and the case died. The ophthalmoscopic appearance of neuro-retinitis descendens usually indicated an acute stage of a meningitis, and as the brain disease advanced and tissue changes supervened, with degeneration, the neuro-retinitis subsided. These objective appearances assisted very much in deciding the plan of treatment to be pursued. Mastoiditis often occurred in the lake region where he resided and he had lost cases with this disease, the attack often being so sudden and severe that little could be done. The cases always had, or had previously had, an offensive otorrhœa, were having chills at very irregular intervals and as the disease advanced would have pain about the ear, general temperature increased, diarrhœa, and also perhaps a hobbling pulse and slight bronchitis. He had never trephined, but had succeeded by poulticing the mastoid night and day with flaxseed-meal poultices applied as hot and moist as the patient could bear every half hour, in relieving the pain and urgent symptoms, and causing the mastoid to suppurate enough in forty-eight hours, or so, to show where it should be opened, when a stout scalpel was sufficient to do so. He also advised large doses of quinine, stimulants, and proper food. If he should ever have a case in which the symptoms were urgent, and poultices did not cause the mastoid to suppurate, he would not hesitate to trephine. He thought the application of leeches for pain, in such cases, contra-indicated as too depressing, the patient could not afford to lose any blood—opium was much better. He thought also that sulphide of calcium was contra-indicated in such cases, because it accelerated suppuration in every part of the body where it might be going on. If pericarditis had commenced, it increased it; if purulent foci were being deposited in the lung or liver, it increased the suppuration about them. He thought the picture presented by such a case was one of general disease like pyæmia, and the local indication was to open and remove the poison as quickly as possible from the mastoid.

Dr. E. E. Holt, of Portland, Me., reported a case of

TERATOID TUMOR OF EACH LOBE; SEVENTH RECURRENCE, WITH DIAGRAMS.

The patient was a young woman, 29 years old, of light complexion, and good average health. The morbid growths were of unusual interest in several respects:

1. They followed promptly perforation of the lobe and wearing of gold earrings.
2. They have repeatedly recurred during a period extending over twenty years.
3. They have undergone remarkable change in structure.

In proof of this latter assertion, a portion was read of a letter from Dr. J. H. Ripley, of New York, who had removed the tumors several times, and who stated that they contained nothing but dense, interlacing, fibrous tissue; and an exhaustive examination by Dr. Edward Preble, of Portland, Me., who found that the said tumor contained germinal matter in abundance, with the following tissues: myxomatous and adenoid tissues, giant-cells, fibro-plastic tissue, loose areolar tissue with infiltrated fat, innumerable elastic fibres, fine and coarse fibrous tissue, hyaline, reticular, and fibro-cartilage, smooth muscle, fragments of large bloodvessels, well-developed skin with corium, papillæ, rete mucosum and epidermis, hair-follicles, hair and sebaceous glands, together with certain unclassifiable structures.

Dr. E. E. Holt also presented some

OBSERVATIONS ON THE HEARING POWER IN DIFFERENT CONDITIONS.

He gave an account of the examination of the following series of cases: Twenty-four cases of chronic non-suppurative otitis media from private practice; twenty-four machinists, twenty-four boiler-makers, and twenty-four persons with normal ears. The hearing power was tested by the voice, tick of a stop-watch, tuning-fork, and Kœnig's rods, and the average age, ratio of bone to aërial conduction, and the audibility of Kœnig's rods in three series of tests were compared with each other and with the normal ear. It was ascertained that the ratio between bone and aërial conduction diminishes in a corresponding degree to that of the hearing power for the voice, and that the average audibility for the upper limits of Kœnig's rods was quite equal to the average normal of 40,000 v. s. as determined by Dr. Blake. Therefore the conclusion was drawn that the loss of hearing in the machinists and boiler-makers was due much more to a defect in the conducting than in the perceptive part of the organ of hearing, for the following reasons:

1. Because of past history or present condition of catarrh of the middle ear and naso-pharynx.
2. Because the tuning-fork, when placed vibrating in the centre of the teeth, was heard louder and longer in the more affected ear, and the sound of it was invariably increased by pressing on the tragus and closing the meatus.
3. From the fact that, had there been any considerable disease of the labyrinth, they would not have responded so nearly to the normal average audibility for the upper limit of Kœnig's rods, since such an astute observer as Dr. Blake, who has made extensive use of them, has never had a case of labyrinthine disease without a *marked loss of hearing* for the Kœnig's rods.

In regard to hearing in a noise, several of the three series made a voluntary statement that they could hear better in a noise. These were carefully tested in a quiet place and then in a noise, and in every instance there was no improvement of hearing in the noise; on the other hand, when the voice was used at the same tone, it was not heard quite as well in the noise as in a quiet place.

Dr. Ch. J. Kipp, of Newark, made some remarks

ON THE ASSOCIATION OF AURAL DISEASE WITH SIMPLE SPARKLING SYNCHISIS OF THE VITREOUS HUMOR.

He had the records of seven cases of sparkling synchisis, in six of which aural symptoms were present. In the seventh case it was not known whether ear disease was present or not. In five of the cases where the disease was in one eye, the aural affection appeared in the ear of the same side in two cases, in both ears in three cases. In four of the cases the ear trouble was probably situated in both the middle and nerve apparatus. In one case there was chronic suppurative otitis media, which had been preceded for years by impaired hearing without otorrhœa. In the sixth case there was absolute deafness of one ear since infancy. Otological literature contains no record of similar cases, and the author thinks the association of the two affections in his cases may have been merely accidental. He publishes his cases with a view of inducing others to examine their cases of synchisis for aural trouble and thus settle the question.

Drs. Little, Webster, and Knapp stated that since Dr. Kipp at the Fifteenth Annual Meeting made an oral communication in regard to the same subject, they have taken especial pains during the past year to examine all their cases of synchisis for aural disease, but that in every case the result was negative.

Dr. C. A. Todd, of St. Louis, Mo., reported a case of *Anomalous Sebaceous Gland in Immediate Proximity to the Auricle*. Dr. Todd being absent, his paper was referred to the Publishing Committee.

THE SIGNIFICANCE OF THE TRANSMISSION OF SOUND TO THE EAR THROUGH THE TISSUES IN AURAL DISEASE,

was the title of a paper by Dr. S. Sexton, of New York. The conclusions drawn by the author are summed up in this manner: 1. When the vibrating tuning-fork, placed on teeth or vertex, is better heard through the tissues on one side, it simply indicates that the better ear excludes wholly or in part such (tissue) transmission; but it does not prove that the auditory nerve in either is affected. (Of course, if the nerve of audition be gravely affected, sound will not be heard by any method of conduction.) 2. If the conductive mechanism is absent or greatly damaged in one ear, while the other remains more or less normal, aërial transmission will be found to be ineffectual in the diseased ear, while the tuning-fork, allowed to vibrate as before, will, therefore, be best heard in the diseased ear, while its vibrations will be almost entirely excluded from the healthy ear. 3. In labyrinthine disease pure and simple, the middle ear being normal, the tuning-fork would be best heard by aërial conduction, because bone conduction would be excluded. (In those extreme cases where destructive disease of the nerve has taken place, impulses of sound may be appreciated irrespective of either the transmitting or labyrinthine structures; thus the deaf-mute is conscious of the sound of thunder, artillery, drums, stamping with the foot upon the floor, and the like.) 4. If the above deductions be true, we may conclude that the tuning-fork is of but little, if any, value in the differentiation of aural disease, and the same applies to Kœnig's rods.

DR. BURNETT stated that he had found the tuning-fork experiment unreliable on account of inaccuracy of the patients. His experience was very similar to that of Dr. Sexton; he lost reliance in the tuning-fork because he could not rely upon the answers of the patients.

DR. HOLT could not agree with Dr. Sexton in regard to the unreliability of Kœnig's rods. It can at any moment be ascertained whether the statements are false or not. If the finger is placed upon the rod and the patient states that the vibrations are still perceived, there is of course a wrong statement, and as it is easy to interrupt the vibrations at any time this becomes an excellent means of control.

DR. KIPP had in the last years lost reliance upon the tuning-fork for the same reason as had Dr. Burnett.

DR. SEXTON exhibited

PHOTOGRAPHS ILLUSTRATIVE OF AURAL DISEASE.

The photographs included perichondritis, facial paralysis from aural disease, ear closed from adhesions during granulation, tumor of the dura mater extending through the temporal bone, fatty tumor of the ear, sloughing of the auricle from the use of gold rings, fibrous tumor, mastoid inflammation with inflammation of temporal bone, osteoma, hæmatoma auris, spontaeous cure of mastoid disease.

He also exhibited two kinds of syringes for use by patients (one a soft rubber, the other a metallic one), and a curette, lightly curved and roughened on the concave surface for the removal of foreign bodies.

Some objections was made to the use of the metallic syringe by patients, the general opinion of the members being more in favor of Davidson's syringe for this purpose.

DR. H. KNAPP, of New York, reported

AN OBSTINATE CASE OF DESQUAMATIVE OTITIS MEDIA, FINALLY CURED.

The patient, when in her third year, had scarlet fever, and otorrhœa with more or less impairment of hearing. When first seen by Dr. K., in 1876, she was thirteen years old, there were large perforations in both drumheads, moderate discharge. The posterior walls of both meatus were swollen and covered with white, scaly masses, which were insufficiently removed by syringing. The treatment after syringing consisted in dropping lukewarm water in the ear three times daily, and sulpho-carbolate of zinc one per cent., in alcohol twenty per cent., and water eighty per cent. A rapid and great improvement occurred, lasting, however, only a few days. Under different kinds of treatment this condition of alternating improvement and aggravation lasted for years. The perforations of the membrana tympani varied in size, so that sometimes nothing of the membrane could be seen, while at other times it reappeared at the periphery, forming a thick ring with a sharply defined round or oval opening, which at rare and short intervals was closed altogether. Corresponding with this was almost normal hearing power or that power greatly diminished. In the winter of 1880–81 she was advised by Dr. K. to put herself under the charge of Dr. Hackley, to try whether the insertion of an artificial drum membrane by his hands might not improve the condition. And so it did at first, but afterward it became ineffective, and the condition was as bad as before, when in 1882 she returned to Dr. K.'s treatment. He then tried stimulating treatment, cotton pellets steeped in glycerine and nitrate of silver solution. This made the scales detach themselves, the discharge became more profuse and finally polypoid growths projected from the luxuriant mucous membrane. These were removed in two sittings, and a solution of boracic acid in absolute alcohol was instilled. Gradually, improvement took place, discharge became scant, and the swollen membrane assumed almost normal thickness; finally it ceased and the drumhead formed again as a delicate, pale-grayish membrane. When in July, 1883, Dr. K. saw the patient again, the membrane was entirely restored, short process, handle and cone of light could be recognized and hearing was v. $\frac{20}{20}$.

Dr. K. draws from this case the conclusion that desquamative otitis media under palliative treatment may go on, temporarily improving, then becoming worse, bursting the drumhead over and over again, and that this condition will continue until the seat of the disease is laid bare, the luxuriating parts destroyed, and the tympanic cavity and meatus entirely cleaned out. When in his case the character of the disease from being torpid became acute, it could be treated successfully.

DR. THEOBALD asked if the second drumhead was not cicatricial tissue rather than restoration of the drumhead proper.

DR. SEXTON had seen a number of cases where granular tissue came through two or three perforations, and where, for that reason, the membrane could not be seen. After removal of this granular tissue, the membrane cleared up, the perforations closed by a new growth of cutaneous layer, but not of membrana tympani proper.

DR. JONES had seen three cases of entire reforming of the membrana tympani.

DR. THEOBALD thought such cases must be very closely examined. He had often seen partial restoration, and if this would come from many points it might be called a reforming of the drumhead, but not in the sense he alluded to, that is, a normal membrana tympani with all its details.

DR. MCKAY had in no case found reforming of the membrana tympani in the sense of its being a regular drumhead.

DR. MERRILL had seen one case of entire destruction of the drumhead, where in five weeks time it had entirely repaired with perfect hearing power.

The morning session lasted from 10.30 A. M. to 2 P.M.; the evening session from 7.30 to 11.30 P. M. At the close of the evening session the following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. Charles H. Burnett, of Philadelphia.

Vice-President.—Dr. J. S Prout, of Brooklyn.

Secretary and Treasurer.—Dr. J. J. B. Vermyne, of New Bedford, Mass.

Committee on Publications.—Drs. J. J. B. Vermyne, C. J. Blake, J. Orne Green.

Committee on Membership.—Drs. John Green, H. G. Miller, A. Mathewson.

The Society voted to meet next year the day before the Annual Meeting of the Ophthalmological Society, and at the same place.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Nineteenth Annual Meeting, held at Kaaterskill, N. Y., July 18 and 19, 1883.

(Specially reported for THE MEDICAL NEWS.)

WEDNESDAY, JULY 18TH, FIRST DAY.

MORNING SESSION.

THE Society was called to order at 10 A. M. by *the President*, DR. HENRY D. NOYES, of New York, who made a few congratulatory remarks, and then appointed the following committees:

Committee on Bulletin.—Drs. F. B. Loring, of Washington, and E. W. Bartlett, of Milwaukee.

Business Committee.—Drs. John Green, of St. Louis; E. Gruening, of New York; O. F. Wadsworth, of Boston; S. Theobald, of Baltimore; and E. Dyer, of Newport.

The Treasurer's report was read and referred to Dr. David Webster, of New York, who subsequently reported that all the accounts were correct. The report was adopted.

CANDIDATES FOR MEMBERSHIP.

The following were nominated: Drs. Charles S. Turnbull, of Philadelphia; Miles Standish, of Boston; J. L. Thompson, of Indianapolis; W. T. Bacon, of Hartford; Stephen D. Ritchie, of Washington; and John Van Duyn, of Syracuse.

NEW MEMBERS.

The following were elected: Drs. B. E. Fryer, U. S. A., Fort Leavenworth, Kansas; J. A. Andrews, of Clifton, Staten Island; L. Webster Fox, of Philadelphia; J. A. Lippincott, of Pittsburg; J. L. Minor, of New York; and E. E. Holt, of Portland, Me.

INVITED GUESTS.

The following were invited to attend the sessions of the Society: Drs. T. Y. Sutphen, of Newark, N. J.; R. H. Johnston, of Philadelphia; Miles Standish, of Boston; and Swann M. Burnett, of Washington.

The Secretary, Dr. R. H. Derby, of New York, read the resignation of Dr. Thomas G. Morton, of Philadelphia, which was accepted.

INFLUENCE ON REFRACTION OF FOUR YEARS OF COLLEGE LIFE; ILLUSTRATED BY STATISTICS OF THE LAST FOUR CLASSES GRADUATED FROM AMHERST COLLEGE.

A paper on the above subject, sent by **DR. HASKET DERBY**, of Boston, was read by Dr. Miles Standish, of Boston.

The author had been able in 254 instances to trace the refraction through the whole term of four years. The examinations were all personally conducted with glasses, and in the majority of the cases, certainly in all doubtful ones, with the ophthalmoscope. The results given are those obtained by glasses. The use of atropine was entirely impracticable, as the students could not have been allowed even temporarily to be disabled from the active prosecution of their studies. Dr. Derby followed the example of Emmet and Loring in stating degrees of emmetropia as slight as 0.5 D., and included nothing less. The average age of those examined was, at entrance, nineteen years; at graduation, twenty-three. The number of cases was small, it is true, but it is one of the few attempts yet recorded to trace the movement of refraction among the more highly educated during this particular period of life and for a continuous term of years.

The general results were: hypermetropia at entrance 39, at graduation 47; myopia at entrance 90, at graduation 120; emmetropia at entrance 125, at graduation 87.

Analyzing the ametropia he found under the head of manifest hypermetropia, of which there were 39 cases at entrance, 1 changed to myopia, 2 diminished, 27 remained stationary, and 9 increased in amount.

Of the myopia there were 90 cases; 32 remained stationary, 58 increased in amount.

Emmetropia. The observations concerning this class possessed peculiar interest, the results somewhat militating against theories that have found general acceptance. There were at the time of entrance, 125 cases of emmetropia; of these 86 remained emmetropic, 10 developed hypermetropia, and 29 developed myopia. The average age of those thus developing myopia was very nearly nineteen at entrance, twenty-three at graduation. The average myopia developed amounted to nearly 1 D (0.982).

So far as these figures go, they tend to show, first, a large amount of myopia even in this country among the educated classes. The author said it was difficult to compare Dr. Loring's figures with his own, because Dr. L.'s statistics were based upon observations made between the ages of six and twenty-one, and his observations were made between the ages of eighteen and twenty-three; but all researches at the latter age go to prove that at least one-half, or very nearly, of the educated community is myopic in this as well as in other countries. Moreover, contrary to the impressions so long entertained, myopia may be acquired at or near twenty years from the same causes that produce it at an earlier age, and it may continue to progress until the course of study is completed.

The paper was discussed by Drs. Webster and Mittendorf, of New York; Dr. Gruening, of New York, who directed special attention to the use of the term dioptric, urging that some uniform mode of spelling be adopted; Drs. Carmalt, of New Haven; Little, of Philadelphia; and Hutchinson, of Utica.

SOME IMPROVEMENTS IN INSTRUMENTS AND APPLIANCES FOR CATARACT OPERATIONS.

DR. RUSSELL MURDOCH, of Baltimore, read a paper with the above title. He exhibited an ophthalmostat, or a self-holding eye-forceps, and an eye-speculum, which were modified from those exhibited to the Society in 1874. The distinguishing features of the speculum were absence of spring and set screw. The change in the ophthalmostat was so that it seized the conjunctiva in a vertical fold, and rotated the eyeball without dragging it, and the substitution of three little hooks for one pair, which secured greater steadiness.

The new instruments consisted, first, in the combination of Graefe's knife end to end with Wecker's scissors. Second, a combination of iris-forceps with the cystitome and shell spoon.

The advantages claimed for these instruments were, that an assistant is dispensed with, and that seven instruments are reduced to three in performing the modified linear extraction of cataract.

Dr. Murdoch also exhibited a bandage which could be quickly made and easily applied.

DR. GRUENING, of New York, thought that outside of the limits of civilization such complicated instruments might be useful, but that within the limits they should be discarded entirely, and that a cataract operation should not be undertaken without an assistant. Concerning the bandage, he said an ordinary flannel bandage could not be replaced by anything which had yet been brought forward. No bandage can produce the pressure that can be applied by the use of the flannel roller. It is necessary to immobilize the eye, and this cannot be done by any substitute for the ordinary flannel bandage.

The **PRESIDENT** remarked that he had had some experience in the use of the little forceps in fixation, and had long ago discarded the instrument because it did not give so much control over the eye as one might imagine. He had reached the conclusion that the operator's hand should guide the forceps.

DR. MURDOCH said he was well aware the gentlemen in New York could obtain an assistant at any time, but he thought there were occasions outside where it was impossible to secure an assistant, and that the instrument had been devised especially to meet such emergencies.

DR. THEOBALD, of Baltimore, believed that the eye could not be immobilized by any bandage whatever which was at all permissible, and that there was a decided objection to the long flannel bandage, especially during hot weather.

Dr. Gruening said he would not insist upon the flannel bandage, but that he would insist upon the long bandage, and of late he had used gauze, dipping it into water before applying it. He believed that the eye could be perfectly immobilized if the bandage were properly applied. The first thing to be done is to fill up the orbital depression, so that when the hand is placed over it the brow and the bridge of the nose are not felt, but the hand rests entirely upon the pad, and upon that pad pressure with the bandage can be made which will render the eye entirely immobile.

Dr. Theobald thought if Dr. Gruening would apply the bandage in the manner described to his own eye, he would find that the eyeball had not been rendered immobile.

Dr. Henry S. Schell, of Philadelphia, reported a case of

TUBERCLE OF THE IRIS.

The patient was a boy, nine years of age, who applied for treatment at the Will's Eye Hospital, August 29, 1881. The left eye had been painful for four days, and exhibited the general signs of ordinary plastic iritis. Atropine and mercurial ointment were prescribed. On the 16th of September, no effect had been produced by the treatment. In the latter part of October, the boy came to the Children's Hospital, suffering from well-marked coxalgia in the second stage. There was a distinct history of phthisis on the mother's side. The left eye was still somewhat painful, the pupil was immobile, and there was a ring of circumscribed injection, and projecting from the nasal side of the pupillary margin was a small, yellowish-white nodule, the size of a pin's head, and tinged with pink. This nodule gradually increased in size; the hip-joint disease progressed. The eye was enucleated, and was examined by Dr. G. B. Lawrason, of New Orleans, who reported that it consisted of two or three tubercular masses embedded in inflammatory product. The tubercles seemed to have developed in the organized inflammatory product, which nearly filled the anterior and posterior chambers.

The President said that within the last year a case had been under observation in New York which illustrated the difficulties in diagnosis. The patient was four years of age, and the gross appearances presented by the eye were absolutely indistinguishable from a glaucomatous condition or a metastatic choroiditis. The patient continued under observation for several weeks without much progress in the disease. The eye was then enucleated, and tubercular disease was found to be the true nature of the lesion. It was felt at the time by those who examined the patient that, in some cases, the differential diagnosis between glaucoma and tubercular disease is impossible.

TUBERCULOSIS OF THE CILIARY MUSCLE AND IRIS.

Dr. O. F. Wadsworth, of Boston, reported a case of the above character, occurring in a girl three and a half years old. Dr. Hasket Derby, of Boston, saw the patient when the process had lasted two weeks, and regarded it as a case of kerato-iritis. The pupil contracted and remained so in spite of atropia. The cornea was hazy: the lids were natural. Afterwards, when Dr. Wadsworth saw the patient, the cornea was hazy, the conjunctiva was moderately congested, there was no marked ciliary congestion, there was good anterior chamber, and the pupil was of good size. The patient died about six months afterwards. The eye, after it was removed, contained a mass of about six millimetres in thickness, the vitreous was replaced by serous fluid, and there was nothing of the lens to be seen. The iris and choroid were in place, and behind the mass. Microscopic examination, made by Dr. Ernst, of Boston, revealed that the growth was tubercular in character, and he was also able to demonstrate the presence of bacilli. There was no evidence of pulmonary disease. It was learned late in the history of the case that the father and the father's brother died of phthisis, and that other members were subject to bronchial attacks, so called.

The paper was discussed by Drs. Prout, of Brooklyn, and Webster, of New York.

Dr. S. F. McFarland, of Oxford, New York, read a paper on

A PERSONAL EXPERIENCE WITH PRISMATIC GLASSES.

During his boyhood he had slight divergence occurring and disappearing at times, although seldom sufficient to attract attention. Still he had the full use of his eyes, could judge of distance as well as others, and was even expert in the sports of youth requiring binocular vision. He had no inconvenience during his studies, always enjoying the greatest comfort during the most severe and protracted application. During the autumn of 1862, he contracted typho-malarial fever in the army, and after recovering from this he found that he had lost the full and comfortable use of his eyes, which continued with the usual pain and annoyance attending a futile effort to use both eyes in conjunction, and he was compelled finally to discontinue reading almost entirely until, in January, 1866, he consulted Dr. H. D. Noyes, who gave him plain prisms of seven degrees each, bases inwards, for distance, and eight degrees each with plus thirty-six spherical for reading. At that time he had been nearly three years unable to obtain binocular vision even for a moment, but at once he was able to see distinctly. He has never discontinued their use. They have been varied from time to time, but he has always adhered to the prisms. He suffers the inconvenience that he cannot maintain continued binocular vision, but can obtain and retain it long enough for an iridectomy, or the extraction of a cataract, and even during very protracted operations, although at the expense of pain and very distressing lassitude following the effort. Without the prism he could not do these things, inasmuch as slight differences in distance would not be appreciable. With bifocal sphero-prismatic glasses he is able to do all his office work without changing, and with a reasonable amount of comfort.

Dr. R. J. McKay, of Wilmington, Del., said that a music teacher came to him in September, 1879, who while standing directly in front of his class and moving his eyes from right to left extremely without moving his body, weakened the external recti. Dr. McKay ordered prisms with the bases external, which the patient had worn ever since with comfort, for distance only.

Dr. O. F. Wadsworth, of Boston, then read a paper

ON THE APPARENT CURVATURE OF SURFACE PRODUCED BY PRISMS.

The phenomenon is very familiar that when we look through prisms with the bases inward with a plane surface, the surface appears convex, and with the bases outward, the surface appears concave. He had not met with any exception to this phenomenon, and the communication was intended to explain it, and was the theory which had been worked out by Dr. Pierce. It was illustrated with diagrams.

Dr. S. W. Burnett, of Washington, on invitation presented a specimen of

TUBERCLE OF THE CHOROID,

accompanied with the clinical history of the case, which occurred in a colored girl, fifteen years of age.

Dr. J. A. Spaulding, of Portland, Me., then read a paper in which he reported a case of

SYMPATHETIC NEURO-RETINITIS.

The author first referred to the able works of Mauthner and Kneis, whose views are so diametrically opposed, the latter believing that the so-called cases of sympathetic neuro-retinitis are open widely to criticism. It seemed desirable, therefore, to publish and thus to offer to careful criticism every case of apparent sympathetic inflammation of the retina and optic nerve (either alone or conjoined), and above all does this appear necessary when we have, as at present, to offer one in which, so far as accurate and repeated examinations have availed, the retina and optic papillæ of one eye underwent inflammation after an injury to its mate, while at no time from the beginning of the case were there ever any visible signs of inflammation of any portion of the uveal tract. The patient was a Danish woman, fifty-six years of age, and healthy in every respect. On the 6th of January, 1883, she was struck in the eye by the horn of a cow, which rendered her at once and forever totally blind in that eye. The patient saw a flash of light, and then the sight was gone. Eleven weeks after the injury to the right eye, the patient, much reduced in health on account of the pain and irritation in the right eye and its neighborhood, came to Dr. Spaulding for consultation on the 30th of March. About four weeks after first seen, the right eye was enucleated on account of the excessive pain from which the patient was suffering. The operation was followed by excessive hemorrhage, which could not be checked by pressure or hot water, and only ceased after ligature of the artery deep in the orbit, and of a second one, which appeared to spring from a band of connective tissue uniting the globe and upper eyelid. The case subsequently progressed favorably, and the patient was sent home. No medicinal treatment was adopted. The result appears to justify the opinion of the truly sympathetic nature of the neuro-retinitis in the left eye, for the sight gradually returned to the remaining eye. The pain in the head disappeared with considerable rapidity. July 14, 1883, examination with the ophthalmoscope revealed normal left eye, vision $\frac{20}{30}$. The enucleated eye was lost. The presence of this neuro-retinitis with total loss of vision in the eye five weeks after an injury to the other and without any other visible or possible cause, such as idiopathic iritis, syphilis, cerebral lesion, etc., indicates the sympathetic nature of the disease. Iritis was excluded in any form as the possible cause of the difficulty in the left eye.

Dr. Webster, of New York, said he had reported two cases of sympathetic neuro-retinitis in which he enucleated the eye giving rise to the trouble, and with excellent results. The neuro-retinitis subsided, and the eye recovered with much better vision than existed before the operation was performed.

Dr. Prout, of Brooklyn, said, concerning the hemorrhage in Dr. Spaulding's case, that in one instance, after resorting to various methods unsuccessfully, he arrested the hemorrhage by digital pressure with the finger in the orbit.

Dr. Mittendorf, of New York, had employed sponge pressure, that is, applying a good-sized, soft, moist sponge over the orbit, and securing it with a roller-bandage after enucleation — to be worn for twenty-four hours, then changed and worn for the next twenty-four hours; and he had never experienced any trouble from hemorrhage or from infiltration of the lids or the orbital tissues.

Dr. H. W. Williams, of Boston, said he had never had any difficulty in arresting hemorrhage by means of the sponge-tent, and was unable to see how it is possible for hemorrhage to go on if the orbit was properly plugged in that way. However, since he had adopted the circular suture of Bowman, he did not recollect having had a case where it was necessary to apply the sponge-tent.

Dr. Prout thought the removal of the tent would be exceedingly painful.

Dr. Williams remarked that the patients did not like it at all, but the pain could be reduced to its minimum by removing the sponge very quickly.

Dr. Dyer, of Newport, while in charge of an army ward, had between 225 and 250 cases of enucleation, and in not a single one did he experience any annoyance from hemorrhage. He always used a large sponge from which ice-water was gently squeezed into the orbit, rarely for more than ten minutes, and afterwards applied a double thickness of linen, covering it with one thickness of bandage.

Dr. Green, of St. Louis, referred to a case in which ice-water and digital pressure had been employed without success, and finally he tamponed the orbital cavity with a narrow strip of linen, and made external pressure with a bandage which controlled the hemorrhage. The tampon was allowed to remain twenty-four hours, when it was removed without difficulty by a process of unravelling, as it were. He subsequently learned that the patient had a hemorrhagic diathesis.

Dr. Knapp, of New York, referred to a procedure for *avoiding hemorrhage* after enucleation, and it was to keep close to the sclerotic. If this precaution is observed, there will be very little danger from hemorrhage. The most profuse hemorrhage occurs when the optic nerve is cut, because we are likely to go into the natural cavernous tissue of the organ; but the division can be made without undue loss of blood by pressing the speculum into the orbit, and allowing the eyeball to pop out, as it were, which will facilitate the division of the nerve and removal of the ball very materially.

The President had never had but one case of serious hemorrhage, which required digital pressure. He had had one case of enucleation of the eyeball for a tumor in the antrum, and in which the bleeding was so profuse that it was necessary to tampon the cavity with the ordinary kite-tail tampon, made of pledgets of lint. The tampon was effectual, and was readily removed.

The paper was further discussed by Drs. W. W. Seely, of Cincinnati, and F. Buller, of Montreal, Canada.

Dr. David Webster, of New York, then reported

THIRTY-FIVE CASES OF CATARACT EXTRACTION.

They included all the cases which he had had, good and bad, from the beginning, and all the operations were performed at the Manhattan Eye and Ear Hospital. A brief clinical history of several of the most interesting cases was given. Thirty-one different patients were operated upon: males, 20; females, 11. Their ages ranged from 30 to 83 years. Under 40 years of age, there were 2; between 40 and 50, 3; between 50 and 60, 9; between 60 and 70, 9; between 70 and 80, 8; above 80, 2. Twenty-eight eyes were operated upon while the patient was under ether. Of these, 24 were successes; 2 partial successes; and 3 failures. Seven eyes were operated upon without the use of an anæsthetic; 5 of these did well, and 2 were failures. The method of operation known as "Von Graefe's modified," was used in all cases in which it was practicable; where a preliminary iridectomy was done, the incision for the extraction of the lens was made in the same position as in the other cases. Preliminary iridectomy was performed in 6 cases; 4 by himself, and 2 by another surgeon. In only one case of the thirty-five was there loss of vitreous, and this was the only case in which the scoop was introduced into the eye for removing the lens; and in three cases there was dislocation of the lens into the anterior chamber during the preliminary iridectomy. In one case, irido-dialysis was produced during the operation; and in one case the iris fell before the knife, on account of premature escape of the aqueous, and was cut through. In all these cases in which accidents occurred during the operation, the eyes recovered with good sight. In three cases the cornea was thin and flaccid, and became wrinkled or collapsed after evacuation of the lens.

In 2 cases there was hemorrhage from the iris immediately following the iridectomy. In 4 cases a considerable quantity of soft lens matter was left in the eye. In 1 case some inflammatory reaction was noted during recovery. This eye did well. In 4 cases there was iritis. Sloughing of the cornea occurred in 1 case, panophthalmitis in 2 cases, and in 1 there was iridocyclitis with sympathetic inflammation of the fellow eye. A second iridectomy was performed in 2 cases, in both resulting in a clear pupil, but in one failing to restore sight on account of deeper disease. Keratonyxis for pupillary membranes was performed in 7 cases, and in all successfully.

The successes, taking the results of all the cases, complicated and uncomplicated, were 27; partial successes, 2; failures, 6. Dr. Webster believed, however, in justice to himself and cataract statistics, he ought to exclude the cases of extensive corneal opacity, a case of detachment of the retina, and one other case with vitreous and perhaps deeper complications. The figures would then stand, successes, 27; partial successes, 1; failures, 2. By success he meant the standard adopted by Dr. Knapp, namely, v. $\frac{22}{200}$; partial success, ability to count fingers; failures, nothing more than perception of light.

The paper was discussed by Drs. Heyl and Strawbridge, of Philadelphia; Theobald, of Baltimore; and Carmalt, of New Haven.

Dr. W. W. Seely, of Cincinnati, then read a paper entitled

NOTES ON OCULAR THERAPEUTICS.

He directed attention, first, to the use of yellow oxide of mercury in external ocular troubles. Ten grains to the ounce of the vehicle is the best for all purposes. The less bichloride the preparation contains the less pain produced by its application. A practical point with regard to the use of yellow oxide and vaseline in conjunctival affections where there is such profusion of tears as to wash the salve out, was to substitute eserine or the bichloride in solution, to contract the bloodvessels. The strength of the bichloride solution that seems to answer every purpose is one grain to sixteen ounces of water. Such a solution is entirely painless, and has often in his hands set aside an acute catarrhal conjunctivitis of a violent type, after from one to three or four thorough drenchings of the conjunctiva. In corneal affections he uses a four-grain solution of eserine *once a day*, and believes that it acts altogether better than more frequent applications, either of the same or of a weaker solution. This remark applies to all classes of cases.

For the reduction of intra-ocular tension, eserine has for him done away entirely with paracentesis.

Every one has met with cases of iritis in which atropia does not seem to act promptly and satisfactorily, possibly *because of the extreme vascularity of the iris.* In such cases, instead of making paracentesis, and extracting blood, he instils once a day a few drops of a four-grain solution of eserine. The habit of instilling eserine once a day in iritic cases has become a routine practice with him, the patient at the same time using the mydriatic in the ordinary manner. In more than one case had he seen adhesions let go after the combined use of a myotic and mydriatic that had resisted the latter alone. Iritis is the only disease in which he employs a mydriatic as a fundamental remedy.

Eserine is the remedy *par excellence* in corneal affections. In cases in which mydriasis is necessary, the latter can be produced perfectly and still the satisfactory effects of the myotic be maintained. This is illustrated in suppurative inflammation after cataract operations, formerly so unsuccessfully treated by heat and atropine.

Dr. McKay, of Wilmington, Del., had used yellow oxide of mercury, with very favorable results in conjunctival troubles.

Dr. Gruening, of New York, said the alternate use of mydriatics and myotics for breaking up adhesions was not entirely new; he had resorted to this method as long ago as 1868. He regarded the use of eserine in iritis as an extremely dangerous practice.

Dr. Knapp, of New York, thought the alternating use of eserine and atropine was advantageous in some forms of iritis, especially the serous variety. Again, where there is increase of pressure which produces intense pain, as in certain cases of glaucoma, the pain is considerably relieved by one drop of eserine. In serous iritis the pressure is sometimes intense, and he thought that eserine could be so regulated as to prevent the noxious effects of the drug.

Dr. Seely said he did not speak of the alternate use of eserine and atropine, but wished simply to speak of the use of eserine *once a day* for the purpose of contracting the "bloodvessels," of course, maintaining mydriasis by atropine. He had never seen a case in which eserine had produced iritis.

The paper was further discussed by Dr. Kipp, of Newark, Dr. Knapp, and Dr. McKay.

The Society then adjourned, to meet at 8 P. M.

Evening Session.

The Society was called to order by the President.

The minutes of the morning session were read and approved.

Dr. W. F. Mittendorf, of New York, then read a paper on

THE TREATMENT OF DETACHMENT OF THE RETINA.

During the last three years, he had treated several very extensive detachments of the retina, occurring in patients that had only one useful eye, the other being entirely blind or absent. Although no new remedy or new method had been used, it was the combination of the different plans devised for the treatment of this affection, and the mode of administering the remedies that had led to the success. After briefly referring to the causes of detachment of the retina, the writer stated that the object of the treatment must be, (1) to keep the eye as free as possible from all irritating influences, which is best done by closing both eyes, or by putting the patient into a dark room; (2) to keep the eye as quiet as possible, and to avoid all accommodative efforts, and for this purpose the eye must be kept under the influence of a mydriatic; (3) to place the absorbents in the most favorable condition; this is accomplished by means of a pressure-bandage, and he had found elastic pressure, procured by means of a rubber bandage, to be of the greatest assistance; (4) to hasten the absorption of the effused fluid if this be the cause of the detachment—this can be accomplished by the use of jaborandi or pilocarpine. He had given a hypodermic injection of one-fourth to one-sixth of a grain of pilocarpine early in the morning, and then kept up the diaphoresis by the use of an infusion of jaborandi leaves, from forty grains to one drachm to twelve ounces of water, administered in wine-glass doses during the afternoon and evening. This treatment should be kept up for three or four weeks. He had not seen a single case in which the remedy, administered in this way, had to be discontinued on account of unpleasant symptoms.

If the detachment complicates a specific choroiditis, or if it follows a serous iritis demanding specific treatment, this may be used at the same time with the other remedies mentioned. In these cases the disease yields, as a rule, sooner than in other cases, and it will not be necessary to push the pilocarpine to so great an extent.

Dr. Mittendorf then reported in detail three cases, all of which were successfully treated. They tended to show, *First*, That in marked detachment of the retina the energetic use of jaborandi and pilocarpine will do good, especially if the patient can be kept under the influence of the drug during the entire day and for a period ranging from twenty to thirty days; *Second*, That the elastic pressure-bandage must be used at the same time; *Third*, That the patients must be kept upon the back most of the time; and *Fourth*, That the use of atropia, which is employed without causing any inconvenience to the patient, should likewise not be neglected.

The paper was discussed by Drs. Gruening, of New York, Little, of Philadelphia, Andrews, of Clifton, Staten Island, Webster, of New York, Theobald, of Baltimore.

Dr. Spaulding, of Portland, Maine, spoke of the operative treatment in these cases. He referred to a suggestion made by Mooren, that an attempt be made to remove the effusion by means of the hypodermic syringe. Having a case on hand, he tried the operation. Although he succeeded in removing a considerable quantity of the subretinal effusion, there was not much improvement except temporarily. He suggested that the method might be cultivated by placing a piece of rubber tubing between the needle and the tip of the nozzle; thus making an instrument somewhat similar to that used in the treatment of soft cataract. At least, he thought that some form of aspiration might be made applicable in these cases.

Dr. William S. Little, of Philadelphia, then reported two cases of

CONGENITAL ECTOPIA LENTIS: ONE SYMMETRICAL, THE OTHER NON-SYMMETRICAL.

The first case occurred in a man, twenty-three years of age. The non-symmetrical position of the lenses in this case was of interest, and the question arose as to what influence glasses which the patient had worn might have had in producing divergence in the left eye which is now going on, the right eye doing the work. The immunity for three years, and freedom from trouble, favored strongly the opinion that the glasses had not entered as a factor in the etiology of the divergence.

A sketch of a case by Dr. J. M. Taylor, which occurred in the practice of Dr. C. S. Turnbull, of Philadelphia, was also presented. The patient wore glasses with comfort for more than a year, when he was accidently killed.

The paper was discussed by Dr. Mittendorf, of New York, who related the history of a case.

Dr. George T. Stevens, of New York, then read a paper on

THE EMPLOYMENT OF NITROUS OXIDE AS AN ANÆSTHETIC IN OPHTHALMIC OPERATIONS.

He had employed it in operations about the nasal duct, iridectomy, cystotomy, and similar short operations, and believed that it possessed several advantages, such as being less dangerous, unattended with nausea and other symptoms which are incident to the use of ether, and that it demanded for its administration far less trouble than ether or chloroform. He thought it doubtful if it could be relied upon for cataract operations.

The President had employed it more or less during the last ten years, and stated that the nitrous oxide had the advantages claimed for it to a certain extent. He had, however, noticed two features: first, there is likely to be a good deal of rigidity on the part of the patient in some cases. Second, it is liable to be attended with a great deal of venous congestion which gives rise to considerable hemorrhage in wounds about the eye.

Dr. R. H. Derby, of New York, had employed the nitrous oxide preliminary to prolonged anæsthesia with ether, and with very gratifying results.

Dr. Buller, of Montreal, said that for some time nitrous oxide was used in the hospital in London, but with unsatisfactory results. He had resorted to the primary anæsthesia produced by ether with exceedingly gratifying results.

Dr. Albert G. Heyl, of Philadelphia, then presented

A CONTRIBUTION TO THE OPERATIVE TREATMENT OF GLAUCOMA.

After giving the ordinary method of treatment employed, and detailing the history of a case which had been under his observation, and in which he had resorted to operative treatment, he recommended the following plan as a modification of that which he had employed: It was to ligate the frontal artery and then open the supra-orbital artery and allow a few ounces of blood to escape, and then close the vessel with a ligature. He discussed at considerable length the physiological basis of the operation, and said that he wished simply to place upon record a piece of clinical experience which he thought would shed some light upon the condition of acute glaucoma. The patient upon whom he operated was suffering from chronic glaucoma when he saw him, but the case had been one of acute glaucoma in its inception.

Dr. Webster, of New York, recalled a case in which a California surgeon advocated ligature of the carotid early for glaucoma; performed the operation once and cured his patient.

The President stated that the natural history of acute glaucoma must be considered before deciding with reference to the influence produced by any modification of the circulation by operation.

Dr. Seely, of Cincinnati, said it should be borne in mind that the influence of the California operation was directly the reverse of that suggested by Dr. Heyl.

Dr. Gustavus Hay, of Boston, then read a communication on the *Astigmatic Pencil*, which was discussed by Dr. Knapp, of New York.

Dr. Charles J. Kipp, of Newark, New Jersey, then reported cases of

SARCOMA OF THE CHOROID, WITH INTERESTING CLINICAL FEATURES.

Case I. was that of a woman, seventy years of age, first seen six weeks before the eye was removed. Sight had been lost only a few months. There was no pain, nor was there any sign of inflammation of the outer parts of the eye. In the outer half of the eye, behind the lens, was seen a large white mass, of rounded form, on the surface of which were numerous hemorrhages. The retina was detached in the inner half. The diagnosis of intra-ocular tumor was made, and enucleation advised. Four weeks later, symptoms of secondary glaucoma developed, and after the patient had endured the pain for two weeks, she consented to have the eye removed. The operation was not attended by accident, and the wound healed rapidly. On examination of the eye, a large dark tumor was found which nearly filled the eye, and which had started from the outer half of the choroid; it was covered in part by the retina, and extended anteriorly to and involved the ciliary body; it consisted of spindle-shaped cells, and contained much pigment.

Case II. was that of a man, thirty-four years of age, who was first seen seventeen months before enucleation was performed. At that time, the anterior parts of the right eye were apparently quite healthy. On the nasal side of the eye, a semi-globular protuberance was seen to project nearly to the visual axis; upwards and downwards it extended apparently nearly to the vertical meridian; anteriorly, it did not reach quite to the ciliary processes. The tumor was of a greenish-red color, and was covered by transparent retina; its surface was smooth, and its vessels were distinctly visible. The retina was slightly detached at the base of the tumor, but nowhere else. The optic disk was very pale, and its margin slightly blurred. The other parts of the choroid and retina presented nothing abnormal, except an atrophic patch in the choroid below the disk. Tension was normal; visual field defective in outer half, and much contracted, upwards, downwards, and inwards. The other eye showed numerous atrophic spots in the choroid, and pigment deposits in the retina. From the patient it was learned that twenty years ago he had had a severe attack of some eye disease, which seriously impaired the left, and somewhat the right eye—the one now containing the tumor. Since then, his sight remained the same until two months ago, when he noticed that his right eye failed. The disease from which he suffered twenty years ago was doubtless a choroido-retinitis, the results of which were plainly visible in both eyes. Seventeen months later, the patient was seen again. There was now great pain, and the eye presented the usual symptoms of secondary glaucoma. The eye was enucleated, and the wound healed rapidly. On examination, the tumor was found to have started from the choroid in the region of the macula lutea. It was very large. The retina was detached completely. The microscopical examination of the tumor showed it to be a spindle-celled melano-sarcoma.

Case III. was that of a woman forty-one years of age, who was first seen fifteen months before the eye was enucleated. At the first examination nothing abnormal except a prominence and opacity of the retina at the macular region was found. The retina for a space of about two diameters of the optic disk was grayish, and the retinal veins here were dark in color. The summit of the prominence was best seen with a + 4 dioptric glass. The retina was not detached, neither over the prominence nor anywhere else. The eye was as it had been, practically blind for some months. The case was seen from time to time for two months, during which period no marked change in the eye was observed. Thirteen months later she was seen again. She had secondary glaucoma, which had come on about two weeks before. The eye was enucleated and the wound healed rapidly. On examination a large tumor of irregular form and with very broad base was found, which had originated in the region of the macula lutea, and from there spread over the optic nerve entrance.

Case IV. A woman, forty-two years old. Sarcoma of the ciliary body and iris. Secondary glaucoma was present when the patient was first seen. The tumor did not extend to the choroid, and the microscopic examination showed that it had probably originated in the connective tissue of the ciliary muscle. It was composed of spindle cells, and contained much pigment. Five years after the operation there was no relapse.

OSSIFICATION OF THE CHOROID.

DR. KIPP also read a paper describing a case of very extensive ossification of the choroid occurring in a young man, who, when first seen ten years ago, had a chalky cataract to which the pupil was everywhere adherent. As there were at that time no symptoms of irritation of the eye, and the case was hopeless so far as sight was concerned, no treatment was advised. The boy had been born with the cataract, according to the mother's statement. Ten years afterwards the eye became painful, and presented when then seen the appearance of irido-cyclitis. The eye was removed, and, on examination, the osseous plate lined the inner side of the choroid as far as the ciliary processes.

The communication was discussed by Dr. Howe, of Buffalo, who presented a specimen; the President, and Drs. Mittendorf and Webster, of New York.

DR. S. THEOBALD, of Baltimore, then read a paper on

TRITURATION OF THE CORTEX.

He reported two cases in which this operation was practised in connection with preliminary iridectomy to hasten the development of slowly ripening cataract. The operation consists in a kneading or bruising of the anterior cortical layers of the lens by pressure on the cornea after iridectomy and while the anterior chamber is still empty, and in accordance with the suggestion put forth by Prof. Förster, of Breslau. The trituration was done with the angle of the strabismus-hook, and in the first was imperfectly performed. In the second case the operation was performed with the smooth end of the Bowman's tortoise-shell cataract-spoon, which seemed better adapted to the purpose. In the first, the operation was followed by but slight change in the condition of the lens. In the second case, however, a very rapid development of the cataract ensued. In each case there occurred a sufficient amount of iritis to cause slight but persistent adhesions between the iris and lens at the pupillary angle of the coloboma; and in the second case it was found by oblique examination, a day or two after the operation, that near the cut edges of the iris the pigment layer had been detached from the muscular coat in a manner which was quite peculiar. That the iris should be more or less bruised, as well as the lens, however carefully the trituration be performed, appears unavoidable, and the risk of exciting inflammation in this manner seems the chief objection to the procedure. It would appear, however, that Prof. Förster has not had serious trouble from this source, as he makes no special reference to it in his paper.

DR. GRUENING, of New York, had performed the operation twice during the last year. In the first he performed a large iridectomy upward, and with the angle of the strabismus-hook treated the lens in the *area of the pupil only*. No iritis followed, and the lens became completely opaque within one week. He extracted it three weeks later, with very good results. In the second case he performed iridectomy upward, and again treated the lens only in the area of the pupil, and in four days the lens was completely opaque. He thought there were certainly cases in which the operation was indicated, and was attended with great gain.

DR. KIPP said that he performed the operation some time ago. The lens became opaque, and four or five days afterward it cleared up again.

DR. MITTENDORF, of New York, thought the operation was indicated, especially in certain cases in which two cataracts were formed, and his experience in the operation had been equally favorable with that reported by Dr. Gruening.

Dr. Knapp, of New York, had performed the operation once, but it did not seem to hasten the ripening of the cataract.

Dr. Wadsworth, of Boston, had performed the operation once in a patient eight years ago. There seemed to be no effect at all so far as ripening of the cataract was concerned. He thought that probably in some cases maturity of the cataract might be hastened very much by the method, while in other cases probably the result would be very slight.

The President had operated eight times, and in seven cases had subsequently performed extraction. In one case marked iritis developed, but did not interfere with the subsequent recovery, and extraction was entirely satisfactory. He hoped to make a communication upon the subject which would embrace the history of all his cases with remarks.

Dr. Gruening remarked that by the area of the pupil he meant the new pupil, including the coloboma.

The paper was further discussed by Drs. Webster, of New York; Fox, of Philadelphia; Dyer, of Newport; and Theobald.

Thursday, July 19th, Second Day.

The Society was called to order at 9 A.M. by the President.

The Treasurer moved that the annual assessment be five dollars. Adopted.

VASELINE CERATE A CONVENIENT BASIS FOR OINTMENTS INTENDED FOR APPLICATIONS TO THE EYELIDS.

Dr. Theobald, of Baltimore, read a brief paper on the above subject, in which he stated that he had been using with much satisfaction for several months, both in private and in hospital practice, as a basis for ointments intended for application to the eyelids, a cerate made of yellow wax and vaseline, which is prepared without difficulty by melting the wax and vaseline together by gentle heat, and stirring the mixture until it hardens, combining one part of yellow wax with four of vaseline, which proportion gives the ointment sufficient firmness, except, perhaps, in very hot weather, when the proportion of wax may be increased to one to three. Dr. Theobald also exhibited a specimen of ointment of the yellow oxide of mercury, containing two grains to one drachm of vaseline cerate, which, though prepared nearly four months since and kept with no special care, still retained its bright yellow color, and had undergone no appreciable change. He had been told that cerates prepared by vaseline were in use, but was not aware that attention had been called to the convenience of employing them in the manner suggested.

Dr. H. Knapp, of New York, then read a paper in which he reported a case of

BLINDNESS FROM RETINAL THROMBUS IN CONSEQUENCE OF FACIAL ERYSIPELAS.

There is on record a certain number of cases of blindness in consequence of facial erysipelas. Their symptoms vary considerably. There is lack of ophthalmoscopic examinations during the first stage of the affection. Not long ago Dr. Knapp had the rare opportunity of observing such a case almost from the beginning to the end. Mr. E. F., forty years of age, had lived in the tropics, had had syphilis with secondary and tertiary symptoms, which were aggravated, when his business called him north. On the 2d of March, 1883, while in New York, he had an attack of erysipelas, which began upon the nose, and proceeded to the pharynx, cheeks, and orbits. The patient was under the care of Drs. Gulecke and Schottke, who kindly allowed Dr. Knapp to publish the case. The erysipelas progressed, and on March 28th he was totally blind in both eyes.

Reserving a detailed discussion of this case for publication in the *Archives of Ophthalmology*, Dr. Knapp restricted himself to the following remarks:

First. The blindness was produced by compression of the central retinal arteries and subsequent thrombosis of the retinal veins, both having been directly observed with the ophthalmoscope one day after the occurrence of the rapid, almost sudden, loss of sight.

Second. The ophthalmoscopic appearances observed from beginning to end showed no neuro-retinitis, but the successive stages of a thrombosis.

Third. The degrees of the swelling of the orbital tissue, or the establishment of collateral circulation from the choroid, permitted the return of a limited flow of blood into the retinal arteries, which, however, impeded by the blocked veins, led to renewed extravasation to the thrombosis and shrinkage of the arteries, and finally to atrophy of the optic nerve.

Fourth. Perivasculitis played no, or only an unimportant, part in the pathology of this case.

Fifth. The white segments in the veins and arteries were white thrombi and hypertrophy of the walls of the bloodvessels.

Sixth. The thrombus was present in all probability also in the orbital veins, but did not, as in other cases, extend to the cerebral sinuses.

The paper was discussed by **Dr. Kipp**, of Newark, who stated that in the cases in which he had seen the condition described by Dr. Knapp, the retina and its immediate vicinity was in a state of inflammation, or at least opaque, but not between the veins.

Dr. Knapp thought that the segments of the veins, becoming white, could be used as a diagnostic symptom of embolism.

The President had seen a case in which the process was confined more particularly to the optic nerve, with swelling and neuro-retinitis, and subsequent atrophy, and nearly absolute blindness.

Dr. Seely, of Cincinnati, had seen a case in which iodoform, used as a dressing, had produced facial erysipelas in three distinct instances.

Dr. Knapp felt certain that the iodoform had no unfavorable influence whatever in his cases.

Dr. W. H. Carmalt, of New Haven, Conn., read a paper on

CHANGES IN REFRACTION RESULTING FROM A BLOW.

R. A. S., twenty years of age, student in the sophomore class in Yale College, myopic since twelve years of age, consulted him on October 23, 1882, stating that, while practising in the gymnasium the day before, he had fallen violently forward, striking his right eye upon a bolt projecting from the floor. The blow was sufficiently severe to give rise to disturbance that obliged him to keep quiet for the remainder of the day and evening, neither going about nor studying; but at the time of his visit he felt quite well again, except with reference to his eye. Wearing his glasses habitually for all purposes of vision, near or far, he now felt an uncomfortable sensation in looking through his right glass, and could see much better at distance without it, better, indeed, than he remembered ever to have seen before without glasses; but, for all that, he had a very confused sensation when looking with both eyes either with or without glasses. Four months afterwards he was again consulted, when he found, on ophthalmoscopic examination, that there was no conus at the nerve, nor other evidence of retino-choroidal trouble. By oblique illumination, no opacity of the lens was detected. On the following day he saw, at Dr. Carmalt's suggestion, Dr. Loring, of New York, in consultation. To summarize the facts of this, to his knowledge, unique case, it seemed established that in a case of myopia of very considerable and nearly equal degrees in the two eyes, one was reduced by the impact of a blow to a condition of astigmatic myopia, which resolved itself finally into a cross astigmatism without any loss of acuity of vision or range of accommodation. After endeavoring to account for the mechanism of this change, five possibilities presented themselves: *First.* A change in the shape of the cornea. *Second.* A diminution or shortening of the axis of the globe. *Third.* A displacement or dislocation of the lens backward. *Fourth.* A change in the relative position or arrangement of the lenticular fibres. *Fifth.* A preëxisting spasm of accommodation, the tonicity of which had been released by the paralytic effect of the blow.

Dr. Carmalt excluded, as did also Dr. Loring, change in the length of the eyeball, also dislocation of the lens, also the previous existence of spasm of accommodation. The remaining alternative cannot be urged from any knowledge we have of such a condition having been positively determined. It is urged rather as a refuge. All the other explanations having been disproved or not being satisfactory, is it not possible that a sudden and violent impulse could have shaken and so displaced the lenticulate articulations of the lens fibres that they became fastened in a position to correspond to (or cause) the error of refraction indicated above?

The paper was discussed by Drs. Knapp, Noyes, Seely, Webster, Buller, McKay, and F. B. Loring.

DR. E. W. BARTLETT, of Milwaukee, Wis., then read a paper entitled

A FURTHER MODIFICATION IN CATARACT EXTRACTION.

The modification proposed is to make two preliminary iridectomies in certain difficult cases, one upwards and one downwards. Dr. Bartlett then reported two cases which illustrated the modification. The modification was suggested in difficult cases only; as when the eye is very prominent; when the iris does not react to atropine, or attachments have formed between the iris and capsule; when the other eye has been lost and the least amount of risk should be taken with the other eye; and when the patient is very infirm and danger from shock is very great; and when the cataract is maturing very slowly. In such cases this modification gives the patient a better chance of securing a certain amount of sight than the method of making the whole operation at one time.

DR. GRUENING, of New York, then read a paper entitled

BLEPHAROPLASTY ACCORDING TO THE ENGLISH METHOD.

A young man sustained an injury of the face by the explosion of a petroleum lamp. As a result of the mishap the integument of almost the whole forehead, the right temple, the right cheek and corresponding half of the nose was changed into dense cicatricial tissue. The upper lid was wholly everted and its free border attached to the supra-orbital margin. To correct the deformity, the lid was detached from the orbit, the neighboring tissues undermined, the deep scar exsected, the free border of both lids brought in apposition, and united by free sutures. The surface of the wound measured forty millimetres in the vertical, and fifty-five millimetres in the horizontal direction. In order to cover the defect, a flap was transplanted from the inner surface of the left arm and placed upon the wound. The flap was prepared according to Wolfe's suggestion, *i. e.*, deprived of its subcutaneous cellular and adipose tissue. After careful coaptation of the flap to the edges and the surface of the wound, goldbeater's skin and a bandage were used to maintain the flap in its position. No discoloration, no displacement of the flap ensued; it united firmly with the wound, and the ectropion was corrected. To-day, *i.e.*, nine months after the operation, the flap measures fifteen millimetres in the vertical, and thirty millimetres in the horizontal direction. The shrinkage took place during the first four weeks after the operation; no further shrinkage during the last eight months. The result is very satisfactory, and would not have been obtained by any other method.

The paper was discussed by Drs. Wadsworth, of Boston; Kipp, of Newark; and Andrews, of Staten Island.

DR. MCKAY, of Wilmington, then reported a case of

LOSS OF AN EYE FROM SEWER GAS AFTER EXTRACTION OF A CATARACT.

John H., a German, brewer, sixty-one years of age, was operated upon April 16, 1882, for senile cataract without an anæsthetic, by Graefe's method of linear extraction. The upward operation was performed satisfactorily, and without any accident whatever. He counted fingers immediately after the operation. The eye was covered with absorbent cotton and a light flannel pressure-bandage, without the further introduction of a mydriatic. Three and a half days after the operation, the bandage became somewhat loosened; this eye was examined, and atropia was introduced. The incision was closed; the cornea was clear; the papular field dark; and vision, tried for a moment, was very encouraging. The patient subsequently developed symptoms of some general disease; evidence of the contamination of the atmosphere by sewer gas was detected; and finally the eye was lost, as Dr. McKay believed, in consequence of the poisoning of the general system produced by this noxious agent.

DR. MCKAY also reported a case of

SYMPATHETIC NEURO-RETINITIS OCCURRING DURING PREGNANCY.

The patient was twenty-six years of age, and had been married ten months. In infancy she had scarlet fever, since which time the right eye had been weak. Five years ago the eye was treated for a painful inflammation by an oculist in Philadelphia, but during the last two years it had not annoyed her. When Dr. McKay saw the patient the eye was in a quiescent state of chronic irido-choroiditis with partially occluded pupil and dense opacity of the vitreous. She complained of her left eye, and reported that after a week's crocheting a sudden pain was felt in it while looking at a white wall. She was debilitated by malarial and pulmonary troubles, and was three months advanced in pregnancy. Ophthalmoscopic examination revealed hypermetropia and a faint opacity of the deep portion of the vitreous, with decided congestion of the optic disk and retina, and within two weeks the appearance of sympathetic neuro-retinitis was fully manifested, and vision was reduced to counting fingers six to eight inches in a dimly lighted room. After three months' treatment in a darkened room, with a dark bandage over her eyes, and the occasional use of a solution of atropia, to prevent iritic adhesions, inunctions of mercurial ointment to the temples, several leeches to the left temple, and a general sustaining and tonic treatment, she improved in general health, and the vitreous opacity, as well as the exudation of the optic nerve and retina, disappeared, and she recovered good vision. Her pregnancy, Dr. McKay thought, greatly and favorably modified the course of the sympathetic neuritis. The ophthalmoscopic appearances of retinitis albuminurica were looked for repeatedly, but were never found, and the fact of her vision not being again impaired whilst she had general anasarca, which developed later in the progress of the case, enabled him to regard it as a case of neuro-retinitis.

DR. L. HOWE, of Buffalo, then read a brief paper and presented a specimen which illustrated

THE DIFFICULTIES IN MAKING A DIFFERENTIAL DIAGNOSIS IN GLAUCOMA.

The patient was four months old. When first seen, at two months of age, a yellowish reflex was noticed in the interior of the eye which had been previously somewhat reddened, and vision, so far as could be determined, was much impaired. Increase of tension was scarcely perceptible, but after some hesitation it was regarded as plus one. After enucleation it was found that the entire vitreous had contracted into a small cone as a result of previous inflammation, and that the apex touched the retina, and had its interior filled with a semi-purulent yellowish substance.

DR. E. E. HOLT, of Portland, Me., then read a paper entitled

COMMOTIO RETINÆ: OR SOME OF THE EFFECTS OF DIRECT AND INDIRECT BLOWS TO THE EYE.

Dr. Holt reported four cases. In two of these the patient was struck more or less directly by a stick of wood, in one by a round rod or cane, and in the other by a flat piece of coal, striking the forehead, nose, and cheek, not hitting the eye itself. In three cases recovery was uninterrupted. In one there was a relapse, vision was reduced to a perception of light for four days, after which it began to return, and in the course of two weeks became nearly normal. Relapse then occurred and vision sank, but not so low as it was after the receipt of the injury, and recovery with a perfect eye took place much more slowly than at first. Dr. Holt gave a detailed history of this case and also of one of the others.

THE PRESIDENT remarked that Dr. Holt had reported four cases manifestly dissimilar in character. From a thorough study of the affection referred to, he had become convinced that commotio retinæ is a phenomenon which had been entirely explained upon the supposition of a fissure running through the optic foramen of the orbit, and is almost entirely a mythical supposition by itself.

DR. SEELY, of Cincinnati, thought the subject could not be dismissed so summarily as Dr. Noyes had supposed. He had reported one case which could not be explained away so readily, because a single application of electricity restored a vast amount of vision, and there was no explanation of the extreme lowering of the vision from which the patient suffered.

DR. KIPP referred to a case in which there was a fracture and subsequent blindness, and suit was brought for damages. The question which arose was, whether the case was one of congenital blindness with divergence, or was it due to injury. On further examination of the patient and the surroundings, he discovered that the mother had the same condition in the corresponding eye, and taking this into consideration, he concluded that the blindness was not due to the injury.

The paper was further discussed by Dr. Gruening, Dr. Knapp, Dr. Wadsworth, and Dr. McKay.

A paper entitled, *Two Cases of Exophthalmoplegia-externa, associated with Disease of the Optic Nerve from Brain Tumor, with an account of the Post-mortem Examination*, by DR. CHARLES STEADMAN BULL, of New York, was read by title, and referred to the Committee on Publication.

INJURY TO THE EYES BY HANGING.

DR. F. B. LORING, of Washington, said that since the series of experiments reported by Dr. Dyer he had seen no communications concerning the effect produced upon the eyes by hanging, except the case reported by Dr. Green, of St. Louis, which was not corroborative. He had had opportunity to observe one case, which he wished to place on record. In that instance both eyes were affected, although one was not affected so markedly as the other.

DR. GREEN remarked that his case was not corroborative of Dr. Dyer's conclusions in a certain sense; but he did not consider it valuable either as corroborative or otherwise, because the time limited for examination after the execution was too short, not being more than one hour.

DR. HOWE, of Buffalo, referred to one case in which he examined the eyes thirty-five minutes after the execution, and was unable to see any change.

DR. R. H. DERBY referred to three cases, which he had already reported, in which there were marked changes in the eye produced by hanging.

COLOBOMA OF THE CHOROID.

DR. MCKAY, of Wilmington, Del., wished to place on record three cases; in one there was coloboma of the iris. Two cases occurred in children, aged respectively seven and ten months; the other occurred in a woman twenty-eight years of age. In the child seven months of age, the coloboma of the iris occurred.

EYE-BANDAGE.

DR. THEOBALD, of Baltimore, presented an additional modification of his bandage, which he regarded as a substantial improvement. It consisted in cutting the eye-piece bias, in order to prevent the tendency to wrinkling.

IMPALPABLE POWDERS.

DR. MITTENDORF called attention to a new method of applying remedies to the eye, namely, in the form of impalpable powders or triturations. He presented several specimens of remedies prepared in this way.

THE PRESIDENT remarked that he had employed homatropin prepared in this way, and had been well pleased with the preparation.

DR. JONES asked if this method was preferable to the disks prepared by Savory & Moore.

DR. WADSWORTH, of Boston, spoke of the loss of power in a solution of eserine. Recently he had found a solution which was three years old, and it still worked perfectly well.

DR. SEELY, of Cincinnati, said that for ordinary purposes he preferred an old solution of eserine to a fresh one.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. H. D. Noyes, of New York.

Vice-President.—Dr. William F. Norris, of Philadelphia.

Secretary and Treasurer.—Dr. R. H. Derby, of New York.

Publication Committee.—Drs. E. G. Loring and D. B. St. John Roosa, of New York.

It was determined to hold the *next Annual Meeting* at Kaaterskill, New York, on the third Wednesday in July.

The Society then adjourned.

CORRESPONDENCE.

A FRAUDULENT PUBLICATION.

To the Editor of THE MEDICAL NEWS.

SIR: I have recently received several letters from physicians inquiring what is my relation to a volume entitled *An Epitome of Medicine, Surgery, and Obstetrics, Including Nervous Diseases and the Diseases* *of Women and Children*, by Alfred Stillé, M.D., etc., D. Hayes Agnew, M.D., etc., R. A. F. Penrose, M.D., etc. Philadelphia: Samuel M. Miller, M.D., Publisher, 1883.

Will you permit me to state that my relation to the volume is that of a professor whose legal rights have been infringed, and whose professional rights have been treated with discourtesy; that the work both misrepresents and perverts my teaching, and has been issued without my knowledge, consent, or approval, and continues to be circulated, notwithstanding my exposure of its real character before my medical class at the close of the last session. I beg to warn all medical men that the "Epitome" is not in any sense "by" me, as its title-page declares it to be, and that I denounce it as being a false and fraudulent publication.

Alfred Stillé, M.D.

Philadelphia, July 20, 1883.

To the Editor of The Medical News.

Sir: I am receiving letters from various sections of the country, asking for information in regard to my connection with a little volume published by a Dr. Samuel Miller, and entitled *An Epitome of Medicine, Surgery, and Obstetrics*, by Drs. Stillé, Agnew, and Penrose.

I have no desire to increase my correspondence, already too onerous, and therefore deem it best to avail myself of the columns of your widely circulated journal to inform my professional brethren that I disown any relation whatever with this miserable piece of literary larceny, published entirely without my knowledge, and only remarkable for inaccuracy, stupidity, and audacity on the part of its author.

Yours, truly,
D. Hayes Agnew, M.D.

Philadelphia, July 21, 1883.

NEWS ITEMS.

BROOKLYN.

(*From our Special Correspondent.*)

Health of Brooklyn.—In the first six months of the current year the total number of deaths was 6674, at a death-rate of 21.4 per 1000. Smallpox had caused 1 death out of 11 cases; measles, 30 deaths out of 1061 cases; scarlet fever, 363 deaths out of 2146 cases; diphtheria, 239 deaths out of 713 cases. Deaths by whooping-cough were 64, and by typhoid fever 32; the cases of these diseases not being fully reported, they are not quoted. The number of vaccinations, chiefly done in May and June, was 4519.

Suicide of a Physician.—Dr. Milligan Patchen, a recent graduate of the Bellevue Hospital College, committed suicide, in New York City, on the night of July 22d, by shooting himself through the head. He was only twenty-five years of age, and had been recently appointed one of the corps of summer inspectors of the Department of Health. No communication was left by him to show the cause of his self-destruction, and his friends state that nothing peculiar had been remarked respecting his conversation or demeanor.

CANADA.

(*From our Special Correspondent.*)

Quebec Medical Board.—The College of Physicians and Surgeons, of the Province of Quebec, held its triennial meeting in the City of Quebec on the 11th, under the Presidency of Dr. R. P. Howard, of Montreal. In the address, reviewing the work of the past three years, Dr. Howard stated that the special prosecutor had instituted forty-nine suits against persons practising illegally. The matriculation examiners of the Board had admitted one hundred and forty-two candidates to the study of medicine and one hundred and fifty-three licenses to practice had been granted by the Board. A lengthened discussion took place on the propriety of changing the present mode of electing the governors of the College, in order to give the country districts proper representation. The matter was referred to the incoming Board. The ballot was then taken for the governors, and after the result was declared, a meeting of the new Board was held, when the following officers were elected for the next triennial period:

President.—Dr. C. E. Lemeux.
Vice-President for Quebec.—Hon. Dr. Ross.
Vice-President for Montreal.—Dr. Kingston.
Secretary for Quebec.—Dr. A. G. Belleau.
Secretary for Montreal.—Dr. F. W. Campbell.
Registrar.—Dr. L. Larue.
Treasurer.—Dr. E. P. Lachapelle.

Cholera.—The latest cable reports announce the appearance of cholera at Alexandria, and the death there of one European from it.

The Khedive and the Ministers have gone to Cairo to make necessary sanitary arrangements.

A Sanitary Commission, composed of General Sir Evelyn Wood, Baker Pasha, and General Stephenson, has been formed. It has decided to establish three additional hospitals at Cairo, and is organizing an ambulance corps.

The Sanitary Commission has decided that all passengers must undergo a medical examination before leaving Egypt, and it is considering permanent sanitary measures to be enforced against vessels arriving at Egyptian ports from Bombay. About Alexandria all business and agriculture has been suspended. Two months' delay in legal judgments has been granted.

At Cairo the disease has broken out among the British soldiers stationed in the Citadel, and the mortality from the disease in the city is very large. On the 21st there were 381 deaths; on the 22d, 295; on the 23d, 427, and on the 24th, 463. The disease is very sudden in its onset, and its victims frequently fall dead in the streets. It is stated that about one-third of the hospital cases die. The epidemic is spreading northward as well as southward.

At Suez the cholera has broken out among the British troops recently arrived from Cairo, and quarantine against arrivals from infected and suspected ports has been renewed. Cholera has also appeared at Ismalia.

The inhabitants of the most infected portion of Bulak have been sent to Tourah, a place ten miles up the Nile, and their houses have been burned. They are surrounded by a cordon, nothing is supplied them, and they are dying of famine. The cholera is spreading among the guards.

Cholera has also appeared at Damanhour, where crowds of people, unable to pass through the cordon, are collected, and are badly lodged and fed.

At Fareskour, eight miles southwest of Damietta, the leprosy has also appeared, and is spreading rapidly.

At Bombay there are serious fears of the outbreak of an epidemic, as during the past week there were thirty-seven sporadic cases.

The English Government has despatched to Egypt twelve doctors who are experts in cholera, and forty have been sent from India to Egypt.

In Paris, inspectors are visiting all the houses in the populous quarters of the city, in order to institute measures to guard against the cholera.

M. Pasteur, we learn, has offered the French Government to organize a commission to investigate the cholera in Egypt, and the Consulting Committee of Hygiene has reported in favor of the proposition. The commission will be composed, it is said, of MM. Rouy and Thuillier, assistants in M. Pasteur's laboratory; Strauss, of the Faculty of Medicine of Paris, and M. Nolacq.

With a view to the prevention of the introduction of the disease into the United States the Secretary of the Treasury, at the suggestion of Surgeon-General Hamilton, of the Marine-Hospital Service, has telegraphed instructions to the American Consul-General in London and the Consul in Liverpool, to appoint at once sanitary inspectors whose duty it shall be to inspect all vessels leaving the United Kingdom for the United States, and to inform by cable the health authorities in this country of all such vessels having disease on board or being liable to develop disease on the voyage.

This action was taken in consequence of the rumor which has reached here, that cholera had appeared in the London docks, but which, happily, has not as yet been confirmed. Full instructions to the inspectors were at once prepared by Surgeon-General Hamilton, and forwarded by the State Department on the Alaska, which sailed on Tuesday. Pending the arrival of these instructions, the inspectors will act under cable advices.

Yellow Fever.—There were thirty-nine deaths from yellow fever in Havana during last week.

The various commercial bodies in New Orleans, a few days ago adopted the following resolution, which was approved by the Board of Health and forwarded to Governor McEnery.

Resolved, That the Board of Health be requested to petition the Governor of the State of Louisiana to have all infected vessels now in the waters of the State removed out of the same, and that he issue his proclamation that henceforth no vessel from any infected port be permitted to enter the waters of the State.

The following resolutions were then unanimously adopted by the Board of Health:

Whereas, There is danger of yellow fever being introduced into New Orleans through unrestricted communication between Ship Island and the coast of the State of Mississippi.

Resolved, That the Governor of the State of Louisiana be requested to call the attention of the Governor of Mississippi to this fact, and urge him to take stringent measures to put a stop to this dangerous intercourse; and be it

Resolved, That the General Government be requested through the proper authority to order that no communication should be held between Ship Island and the Mississippi coast.

Suing for a Diploma.—A member of the class of 1883 of the College of Physicians and Surgeons of Baltimore, who was rejected in his candidacy for a diploma, petitioned the Court to issue a writ of *mandamus* upon the Faculty that they shall issue his diploma to him, claiming that his rejection had damaged his character to the amount of $2,000. After argument before the Court, the judge decided in favor of the Faculty. An appeal has been taken.

President of the Royal Society.—The election of Mr. Huxley as President of the Royal Society, in place of the late Mr. Spottiswoode, has met with warm approbation on all sides, and there is reason to hope that the Society will render still greater services to biological science than before.

Bids for the Hot Springs Hospital.—Bids were opened last week for erecting the proposed Army and Navy Hospital at Hot Springs, Arkansas, in accordance with plans prepared by Surgeon-General Crane, of the Army, and Surgeon-General Wales, of the Navy. The bids range from $60,000 to $120,000. The contract will be awarded in a few days.

Dr. Osler.—Dr. William Osler, Professor of Physiology in McGill University, Montreal, has just been elected a Fellow of the Royal College of Physicians of London. This distinguished honor is a just appreciation of the excellent scientific work done by Dr. Osler.

Royal College of Physicians.—This College gave a *conversazione* in Pall Mall on July 4th. As usual at these meetings the attendance of visitors was large and distinguished. The guests were received by the President, Sir W. Jenner, K.C.B., Dr. Munk, and Dr. Lionel Beale. At an early period of the evening, H.R.H. the Duke of Albany arrived, and was received and escorted round the College by the President and Censors.

Among the many valuable and interesting objects of art exhibited were some Wedgewood chessmen, designed by Flaxman, lent by Dr. Braxton Hicks, and an antique Moscow enamel, lent by Dr. Alfred Meadows. The President exhibited portrait etchings of George Eliot, Stuart Mill, and Carlyle. Dr. Farquharson, M.P., lent the exquisite drawing of the Royal Academy May-Pole Dance, by Linley Sambourne.

The London Medical Society.—The President, Sir Joseph Fayrer, and Council gave a *conversazione* on July 2d, at the new building of the Society, at which the Prince of Wales, Prince Lucien Bonaparte, and other distinguished guests were present.

Professional Knighthoods.—It is stated that the Queen intends to confer the honor of knighthood on Dr. Pitman, Registrar to the College of Physicians, in recognition of his long and faithful services to that important body, and on Mr. Edwin Saunders, F.R.C.S., for many years dentist to the royal family, and a liberal benefactor of the public institutions connected with his profession.

Health in Michigan.—Reports to the State Board of Health for the week ending July 14, 1883, indicate that measles, inflammation of the bowels, cholera morbus, diphtheria, pneumonia, and diarrhœa have increased; and that intermittent fever has decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending July 14, and since, at 21 places; scarlet fever at 13 places; and measles at 23 places.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 16 TO JULY 23, 1883.

Elbrey, Frederick W., *Captain and Assistant Surgeon.*—The leave of absence granted on Surgeon's certificate of disability by S. O. 26, A. G O., January 31, 1883, further extended six months on Surgeon's certificate of disability.—*S. O. 162, A. G. O., July*, 16, 1883.

Powell, Junius L., *Captain and Assistant Surgeon.*—Assigned to duty at Fort Columbus, N. Y. H.—*S. O. 130, Department of the East. July* 18, 1883.

Richard, Charles, *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Adams, Newport, R. I.—*S. O. 130, Department of the East, July* 18, 1883.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIII. SATURDAY, AUGUST 4, 1883. NO. 5.

ORIGINAL LECTURES.

ON THE TREATMENT OF HYSTERIA.[1]

A Clinical Lecture,

BY PROF. DUJARDIN-BEAUMETZ,

MEMBER OF THE ACADEMY OF MEDICINE, PHYSICIAN TO THE HOPITAL ST. ANTOINE, PARIS, FRANCE.

GENTLEMEN: In taking up as my subject to-day the treatment of hysteria, I do not conceal the difficulties of my task. Hysteria embraces a great number of affections of the nervous system, from the so-called "vapors" of hypochondriacal females, to that hystero-epilepsy so recently described by Charcot as the great hysteria. If the domain of this neurosis is immense, its limits are far from being precise, and he would be a bold man who would in all cases venture by a hard and fast line to separate nervousness, hypochondriasis, epilepsy, and even lunacy, from hysteria. So, as Lasègue has very judiciously said, we are not able to-day, and perhaps never shall be able, to give an exact definition of hysteria; we can only affirm that, by its strange manifestations, hysteria has erased the word *impossible* from pathology.

But before entering into the details of the question, I owe you a declaration of principle; it is that, from the point of view of treatment, hysteria, by its very nature, defies all positive and scientific therapeutic rules. This results from two causes: first, the preponderant part which the imagination plays in this disharmony and disordered equilibrium of the functions of the nervous system, and which determines, as a consequence, that oftentimes where the physician, well-informed, conscientious, patient, devoted, fails, the most brazen charlatan will easily succeed. Hysteria is in fact the harvest-field of quacks, the domain of miracles and surprises. A second factor of importance, as having a bearing on the therapeutics of hysteria, is the disposition of the hysterical female to deceive her attendants, a disposition which Dally has characterized by the name *deliré malicieux* (malicious delirium).

This mental condition of hysterical patients, to which Huchard attaches so great an importance, will prompt intelligent females to endure extreme tortures in order to maintain a morbid state which their will alone has engendered. It results from this singular perversity, that every exhibition of drugs and every therapeutic application which has for its end the treatment of hysteria, may be attended with disappointment; and that one can never affirm that a medicament which has given good results in one case of hysteria will give the same results in another case. In a word, in this neurosis every thing may fail, and every thing may succeed.

With these reservations (which it belonged to me to make), I come to the treatment of hysteria, which comprehends three parts—the general treatment, treatment of the attacks, and, finally, the treatment of certain hysterical symptoms.

The general treatment of hysteria is subdivided into hygienic and medical treatment. We will commence with the hygienic treatment. Here the first place belongs to education, as being of prime prophylactic importance. We can, in fact, in the majority of cases, prevent the development of this neurosis, for it is hereditary, and a hysterical mother has a great chance of seeing her children neuropathic or hysterical.

I believe that the education of children, when they have attained the age of eight or ten years, ought not to be left to the mother. I would remove the young child, and particularly the young girl, from a tutelage too indulgent, too tender, and too ill-regulated; the child should never be allowed to witness any hysterical manifestations on the part of her parent, for imitation plays a considerable *rôle* in hysteria.

It is a good plan to place the girl in a boarding-school, situated, if possible, far from the city. I say boarding-school, for isolation is a bad thing in hysteria, and education with other boys and girls, notwithstanding some serious inconveniences, has real advantages in the case of neuropathic children. Young girls with predisposition to hysteria should not be permitted to read exciting novels, fairy tales, etc., which heat the imagination. Even the culture of piano music, and especially organ-playing, has disadvantages which make it desirable, when possible, to interdict these accomplishments. I have seen hysterical patients who have found in the practice of the organ an aggravation of their nervous symptoms, and this as well from the excitement to the nervous centres occasioned by working the pedals with their lower extremities, as by the effect of the music in stimulating their emotional natures.

On the other hand, neuropathic girls should be allowed physical exercises in the open air, horseback riding, gymnastics, even swimming, etc. In fact, their discipline should be fortifying, virile, and severe. I say *severe*, but it will not do to go to the other extreme, and, while interdicting romances and dancing, develop unduly the religious emotions, for it is quite possible to cultivate in them a state of religious mysticism and ecstasy, which is nothing less than the very disease against whose protean manifestations we are contending.[1]

It is generally at the epoch of puberty in young girls, and at the time of the appearance of the menses, that the first manifestations of hysteria occur. Although the old doctrine that would place in the uterus itself the exclusive point of departure of hysteria, and which has given it its name, is to-day abandoned—since we do now and then observe hysterical men, and even in the female this neurosis may develop without any uterine trouble at all—it is none the less true that the uterus plays a preponderating part in this neurosis.[2]

---

[1] Translated from advance sheets by E. P. Hurd, M.D., of Newburyport, Mass.

[[1] Herbert Spencer, in his treatise on Education (Appleton ed., p. 212), has these golden words, which, if they summarize the highest duty of the educator, also convey a valuable lesson to the intelligent physician who would be to his constituency something more than an administrator of drugs. A "self-governing being" is not merely one who is governed by others—it is a being whose lower propensities are subordinated to the higher; in hysteria this subordination is lacking.

"Bear constantly in mind the truth that the aim of your discipline should be to produce a self-governing being; not a being to be governed by others."—TRANS.]

[[2] One of the worst cases of hystero-epilepsy that I have ever witnessed occurred in my practice this very year (February, 1883), and seemed clearly due to retroflexion of the womb. At any rate, after replacing the organ, and applying a suitable pessary, the convulsive seizures, which before had been very frequent, ceased, and

Michelet, in one of his works, has given the following definition: "Woman is a womb, served by organs." This somewhat spiteful definition finds justification in the case of the hysterical female, to whom it is especially applicable, and it may be established as an immutable law, that in hysteria it is during the menstrual period that the nervous symptoms are most accentuated; this period, then, claims your most watchful attention, and your treatment ought always to follow these menstrual epochs. This question of the *rôle* of the uterus leads me to speak of another point of hygienic treatment in hysteria to which great importance has been attached. I refer to continence and to marriage, and I ask you patiently to follow me in what I have now to say touching this debatable question.

Plato compared the womb to an animal which has but one end to fulfil, that of conceiving, and which becomes furious when its functions are not accomplished. From this is derived the doctrine that continence is one cause of hysteria, and that sexual relations are essential to a cure. This doctrine is so much in vogue, here in France, that one needs only utter the word *hysteria* in a family to suggest the idea of excess of continence to those attending on the patient, and in some circumstances this would be taken as an insult. Hence, I advise you to be chary in the use of the word in your private practice, especially in the presence of the family; say that the patient is neuropathic, that she is affected with nervousness, but avoid the word *hysteria*.

This popular opinion is based—bear in mind—on the declarations of medical men, and till recently the majority of physicians who have written on hysteria, and their number is considerable, have maintained the influence of continence on the development of this neurosis. Briquet was the first to take a stand against this way of thinking, and the arguments which he has adduced have, in my judgment, a high cogency. He has shown that when you take under consideration groups of females who from the point of view of sexual relations lead quite opposite lives, nuns, on the one part, among whom continence is the rule, and prostitutes on the other, among whom continence is unknown; he has shown, I repeat, that hysteria is much more common with the second class than with the first. Moreover, do we not see in our hospital services that the greater part of our hysterical patients are women to whom continence is the rare exception, and who have a more than sufficient satisfaction of their sexual wants? I quite agree then with Briquet, and believe that if continence may have a certain influence on hysteria, an influence by no means scientifically demonstrated, genital excitations are quite as detrimental.[1]

Families will often ask you whether young hysterical girls ought to marry; it is best to be non-committal in this matter, and not affirm, as has often been done, that marriage may cure the hysteria. To counsel marriage in such a case is a responsibility which the physician ought not to assume, for it is not proved that marriage ameliorates the condition of a hysterical person, and in order to obtain a problematical benefit he may doom a husband to a life of chagrin and unhappiness.[2]

It would be a curious chapter which should relate the history of the part which husbands have had to play in this deplorable neurosis. The husband of a hysterical woman often finds himself in a sorry plight. However amiable and attractive, however persuasive and commanding, he can neither please nor control a woman of disordered brain, before whose capricious whims he is powerless; whose actions, however seemingly reprehensible, are performed almost without volition and without consciousness. In other cases the husband undoubtedly favors the development of hysteria in his wife by the incessant concern with which he treats her manifestations. By the attentions which he lavishes on her, by the anxious exaggerated affection which he displays, he fosters and encourages the ataxic phenomena. The man is fortunate who, constantly and sympathetically watching the hysterical explosions of his wife, does not, by imitation, become hysterical himself. The spectacle has more than once been witnessed of a neuropathic couple (generally without children) bewailing and intensifying their mutual ailments. Here separation is most salutary to both parties.

Fortunately, the marriage of a hysterical person is not always so gloomy in its results; where especially the husband, by his coolness and firmness, his good-sense and moral influence, gives to the wife a sage and dominant direction, which mitigates and moderates the nervous phenomena. While, then, it may be said that marriage is a good thing for hysterical women, when it brings with it happiness and tranquility, it is nevertheless true that oftentimes those most favored by fortune and surrounding conditions, whose life, calm and peaceful, ought to be without a cloud, suffer from groundless fears and imaginary ills, and are always unhappy beings, and all in consequence of an ill-balanced nervous organization.

There is no kind of life which is exempt from hysteria, and we find this neurosis among the poor and among the rich, those that labor and those that hire; we see continually examples in our private practice, and in our hospital service. The country also furnishes its contingent of hysterical patients. It has been maintained that country life preserves from hysteria. This is a mistake, and we observe instances the most curious and obstinate of this neurosis in our rural villages. Apart from heredity, disappointed hopes are a most prolific cause of hysteria, and whatever the station or occupation in life, depressing cares and disappointments will come.

As occasional or aggravating causes of hysteria, we may refer to two kinds of life diametrically opposite: on the one hand, a too fashionable life, with all its pleasures and all its fatigues; on the other hand, a too solitary life, with all the ennui which accompanies it. In the one case the hysteria is brought on by nervous excitement, in the other by a morbid brooding over neuropathic symptoms which are thereby perpetuated and aggravated. It is important, then, that you should find diversions for your hysterical patients, but such diversions should not exceed certain limits.

As for diet, it should be of a nourishing and unstimulating character. I advise you especially to forbid the use of tea and certain alcoholic liquors. I believe that the abuse of tea is an occasional cause of hysteria, especially where one is not accustomed to it, and I have seen nervous women improve with suppression of this beverage.

Among the wines, you ought especially to forbid heady and sparkling white wines, as champagne, and all the heavy alcohols, particularly absinthe. Lancereaux has, in fact, shown that in alcoholic patients, and especially absinthe-takers, there exist sensory troubles akin to those of hysteria, and it is probable

---

have not since returned. This patient, who was then living at one of our large boarding-houses, was seen by Drs. Snow and Montgomery, of this city, and they can testify with me to the violence and unmanageable nature of the paroxysms.—Trans.]

[1] Briquet, Traité de l'Hysterie, Paris, 1859.

[2] Briquet has shown that marriage has but little modifying influence on hysteria. In 98 cases marriage was detrimental in 50, without influence in 31, and in 17 ameliorating. Bernutz's statistics show that hysteria is a little less common in the married than in the unmarried, but only in the proportion of 7 to 9. *Vide* Briquet, Traité de l'Hysterie, p. 461.

that the greater part of men who are afflicted with hysteriform neuropathic disorders are men who have been addicted to alcoholic stimulants and to absinthe.

I come now to the medicinal treatment of hysteria. This treatment will comprise three parts: the pharmaceutical treatment, the treatment by balneotherapy, and the treatment by electricity and metallotherapy.

The pharmaceutical treatment formerly consisted in the administration of that class of medicaments described under the name of antispasmodics, such as (more especially) valerian, musk, castor, galbanum, and assafœtida. The greater part of these medicaments are to-day almost forgotten, and this for several reasons: first, because their antispasmodic effects are far from being demonstrated, and, in the next place, because they have been superseded by a more active medication, that of the bromides. I shall not, then, dwell on all the numerous formulæ of potions, syrups, pills, ptisans, suppositories, and lavements of supposed antihysterical virtues,[1] for which I refer you to your ancient formularies; but before passing to the bromide treatment, I desire to say a few words about valerian, which still enjoys a certain repute in the treatment of hysteria.

Valerian, the officinal portion of which is the root, is administered in infusion, in tincture (the ammoniated tincture is perhaps the best preparation), in the form of valerianates, and especially of valerianate of ammonia. For my part I have little faith in the therapeutic action of these valerianates, and finish what I have to say of this medicament by adding that the pills of Meglin, so much prescribed for nervous disorders, contain a notable quantity of extract of valerian.[3]

Who says hysteria, says bromide, and at the present day there is not a hysterical person but has taken bromide. The bromide of potassium is the most often employed, but you may also use the bromides of sodium and ammonium in combination with it, constituting solutions of the mixed bromides, of whose effects Charcot has spoken so highly. Here is the formula which I habitually use: R.—Bromide of potassium, bromide of sodium, bromide of ammonium, āā x; water ccl.—M. Signa.—A dessertspoonful to a tablespoonful night and morning.

I do not intend here to enter into details as to the physiological action of these bromides, of which I shall have more to say when I come to the treatment of epilepsy. What I wish now to impress upon you is that these medicaments are among the most powerful depressants of the cerebro-spinal axis, and that it is owing to them that we can control the exaggerated manifestations of the nervous system. If we add that the bromides allay genital excitation, you comprehend all the advantages which we may derive from this precious remedy in the treatment of hysteria; at the same time I am far from affirming that the bromide medication is to be applied indiscriminately to all cases of hysteria, and it is because abuse has been made of this medicament that we see to-day certain physicians maintain that it is rather detrimental than useful in the treatment of hysteria. This is by no means the case; only here, as for other medicaments, it is necessary to know the indications and contra-indications for this bromide treatment. Moreover, you must not fail to keep in mind that whatever may be the relationship between hystero-epilepsy and epilepsy (and some pathologists affirm a very close relationship), there exists, from a therapeutical point of view, a great distinction between these two affections. In fact, while epilepsy is tributary to the bromide medication, this same treatment has never effected a cure of the attacks provoked by hystero-epilepsy.

When the hysteria is accompanied by insomnia, excitement, and, in particular, genital excitement and much agitation, moreover, when the patient is of robust frame, the bromide will give admirable results. On the contrary, when your patient is feeble and anæmic, manifesting her neurosis by gloom and tears, and the nerve-centres are depressed in their action (there being no genital excitation), the bromide can do nothing but harm. The great inconvenience of the bromide results from its depressant action on the nervous system, and patients submitted to this treatment experience such a physical and mental torpor that it is difficult for them to apply themselves to their ordinary tasks.

The acne eruption which often follows the continued use of bromide in large doses is a serious evil, especially to fashionable young ladies, who strongly object to see their faces disfigured with this rash, and sometimes refuse the remedy altogether. I know no means of preventing this bromide eruption, which results from the elimination of the bromide by the skin. I know that it has been claimed that the internal use of arsenic will prevent the eruption, but I have often given it for this purpose with no result whatever.

As for the dose, this varies according to individuals, but, as a guide, you ought always to have recourse to an examination of the reflex sensibility of the velum palati, and your doses should be large enough to obtain, in most cases, anæsthesia of the pharynx. By way of caution, I would advise not to give the bromide for a great length of time, and to occasionally suspend the treatment. For your guide, you have only to follow the evolution of the nervous manifestations. In most cases these manifestations are produced about the time of the catamenia; it is before, during, and after these periods that you ought to administer the bromide, and in such a manner that there may be in each month fifteen days of treatment and fifteen days of rest.

Besides the alkaline bromides, other bromides have been recommended, such as bromide of zinc and bromide of camphor. The latter has been much vaunted these late years, but its action is very uncertain, and it has no efficacy except in cases of genital excitement; as for bromide of zinc, this preparation, little employed in this country, has been highly spoken of by Hammond, of the United States, who advises it especially in epilepsy. Opium plays an important part in the treatment of hysteria, and like bromide, has its advantages and disadvantages. It was my master, Bernutz, who, after Gendrin, extolled especially the opiate medication. He administered laudanum in the dose of two drops twice a day, and gradually increased the dose till forty drops were taken in the twenty-four hours. This treatment is mainly applicable to the asthenic forms of hysteria: I believe it useless and dangerous in the sthenic forms, and you plainly see the indications for the opium treatment are directly opposite to those for the bromide treatment, for opium has an exciting action on the nervous system, while bromide is depressant. Unhappily, this treatment by opium has another disadvantage, in the large doses which one is compelled to attain in these cases, and many hysterical patients become morphomaniacs. In order to avoid these disadvantages, it has been proposed to substitute chloral, but here again you encounter serious inconveniences, for the continued use of chloral in doses gradually increased is very detrimental.

---

[1] Vide Dictionnaire de Therapeutiques, by Dujardin-Beaumetz, article Assafœtida.

[2] This is the formula of Meglin's pills, called compound pills of hyoscyamus and valerian:

R.—Alcoholic extract of hyoscyamus,
Alcoholic extract of valerian,
Oxide of zinc, . āā 10 grm. or ʒijss.—M.
S.—Divide in pil. No. cc.

This question of dose in neuropathic patients is of the greatest interest; hysterical subjects present, as Huchard has well said, a *veritable therapeutical ataxia.* Sometimes they are poisoned by extremely small doses of certain substances, and sometimes they experience no therapeutic effect from really enormous doses. It is well to bear this fact in mind when called to treat a hysterical person. Do not forget, moreover, that there exists from the point of view of medicinal treatment, a moral influence of a direct and positive kind, and that here you will have occasion to witness the triumph of pills of *mica panis*, of potions of the extract of dandelion; in a word, of all those preparations which act on the imagination alone. The history of medicine abounds in cases where, owing to the assurance with which they have been prescribed, these pills and these potions have had the most signal curative efficacy in neuropathic individuals.

By the side of the pharmaceutical treatment, and even above it, is placed balneotherapy, which comprehends three modes of application; baths, hydrotherapy, and mineral waters. Warm baths, and particularly prolonged baths, have a very happy influence in the treatment of nervous disorders, especially in the period of excitation, and Bernutz has greatly vaunted their effects. These baths ought to be of from one to two hours' duration, and the water all this time should be kept at the same temperature. The therapeutic virtues of these baths are augmented by adding infusions of aromatic plants, as melissa or valerian, of which medicated baths Beau speaks in high terms. The good effects derived from these medicated baths are explicable, not on the principle of cutaneous absorption—the skin with its epidermic covering does not absorb medicinal substances contained in baths—but entirely by the introduction through the respiratory passages of the odorous and volatile principles of the herbs employed. It has, as you are aware, been maintained that in order to obtain the therapeutic effects of valerian it must be administered, not by mouth but by inhalation.[1]

Hydrotherapy plays an important part in the treatment of hysteria; it constitutes, with the bromides, the grand basis of the therapeusis of this disease, but it is important that you should know how the cold water should be applied. It is advisable to employ douches with broken jets, and never to use cold douches at the beginning of the treatment, but always tempered douches. The effect on the nervous system of cold water is sometimes so violent in hysterical patients, as to determine such a state of suffocation that after enduring the first cold douche, they obstinately refuse to submit any longer to this treatment. It is well, then, to begin with tempered douches (about 25° to 30° Cent.), and to progressively lower the temperature of the water; it is only when the system is habituated to this mode of treatment that you will be able to give cold douches, or rather alternate douches [douches alternately cold and hot]. These last sometimes have too stimulant an effect and determine hyperexcitation; you must then return to tempered douches. In a word, in your hysterical patients, you ought always to begin with tempered douches, and then, according to the periods of excitation or depression in which your patient is found, you should employ the stimulating action of the alternating douche, or the sedative effects of the tempered douche. You must avoid at first douching the heads of your patients; I have often seen the shower-bath on the head determine neuralgic pains of a severe nature, or quite persistent vertigines. The duration of the douche ought not to exceed thirty seconds.

You will derive from hydrotherapy thus utilized, very beneficial results; cold-water treatment restores not only the sensibility of the skin, as Thermes has shown, but it also promotes the equilibrium of the functions of the nervous system, and nutrition in general. But in order to obtain these results satisfactorily, it is often necessary to remove the patient from her family surroundings, and to place her in some hydrotherapeutic establishment, where the administration of cold water is made with great skill and prudence. And this is a point on which Charcot has justly insisted. Mineral waters have a feeble part in the treatment of hysteria, and generally, as it is the action of cold water that is sought, patients are sent to the hydrotherapic stations so numerous in the centre of Europe, and which especially abound in Switzerland and in Tyrol; stations of which Devonne and Aussèe are types, and which, with the action of cold water, unite all the climatic conditions favorable to the treatment of affections of the nervous system. In France we have a thermal station which enjoys a certain repute in the treatment of nervousness, I refer to Neris; to these waters you may join those of Ussat, St. Sauveur, and Forges les Eaux.

But, while on this subject of mineral waters, I must caution you against the employment of sea-baths in hysteria. I see many of my confrères send their hysterical patients to the sea-side; it is a bad practice. For my part, I have always seen sea-air, and especially sea-baths, attended with such excitation that my. patients were much the worse fer it; so, in my opinion, the hysterical condition contra-indicates the employment of sea-baths.

Electricity is doubtless an element of secondary importance in the treatment of hysteria; nevertheless, it renders us good service. It may, as we shall presently see, arrest the attacks, or diminish their number; it may also modify general sensibility, like hydrotherapy. In these cases, it is especially to static electricity that you should have recourse, as it is this form of electricity, revived by Arthuis, and more recently by Charcot and Vigoureux, which gives the best results. It is here that you should make use of those general electric baths, those electric brushes, and those sparks which I described in my lecture on medical electricity, procedures which constitute what is called franklinization. But there is a kind of medication which has with electricity many points of contact. I refer to metallotherapy, on which I desire to dwell at some length. From the most remote antiquity, medical properties have been attributed to metallic plates, and plates of copper, lead, or gold, applied as veritable amulets to the skin, have had curative efficacy in certain nervous disorders, according to the statements of ignorant pretenders. About the end of the last century, an American physician by the name of Perkins grouped together all the facts from Galen downward, and propounded a medical doctrine which bore the name of *Perkinism.* But almost all of these facts were forgotten when Burq commenced his experiments, and it is to him that we owe the valuable discovery of metallo-therapeutics and the indications which flow from it. The first tentatives of this experimenter were made in 1850, and it was not till nearly thirty years later, after the reports made to the Society of Biology, in 1877 and 1878, by Dumontpallier, that this method entered definitely into the domain of current practice. Burq affirmed that metals applied to the skin restore sensibility, force, and animal heat, and that, according to circumstances little understood, the curative metal varies with individuals. Such a person is sensitive to gold, another to iron, another to copper, etc. etc., and from the results of these external applications of metals he drew conclusions as to the internal administration of metallic preparations, which had the same property of restoring sensation and bodily heat; in a word, metalloscopy led to metallotherapy.

---

[1] Pomme has greatly extolled prolonged baths in hysteria; he regrets that the day is not more than twenty-four hours long, because, that now, he is not able to give them as long as he would like.

Beau and Bernutz advise warm baths of two, four, six, and eight hours' duration.

Bernutz has seen, under the influence of baths six hours long, cataleptic attacks that have lasted six or eight months disappear completely. (Pomme, Traité des affections vaporeuses des deux sexes, Paris, 1883. Bernutz, art. Hysterie, in Nouveau Dict. de Med. et de Chir., 1873.)

The experiments made in this direction by the Committee of the Society of Biology, under the supervision of Charcot and Dumontpallier, brought to light a great number of new facts; they showed that troubles of sensibility, limited to one-half of the body, might, under the influence of these metals, be transferred to the half not affected, thus illustrating what has been described as the *law of transfer*.

It was also discovered that metals were not the only bodies capable of modifying sensibility, and the number of æsthesiogenous substances, as they are to-day called, increased sensibly. Charcot and Regnard, taking up again the first experiments of the end of the last century, noted the æsthesiogenous properties of magnets. Vulpian showed that electricity, applied to a very circumscribed part of the cutaneous surface, possessed the same properties. Then Grasset, with the vesicatory; Thermes, with cold water; Parona, with metallic salts; Seure, with dried collodion and cellulose; and Lannois and Huchard, with jaborandi, obtained the same results. I myself, in my hospital service, have shown, as Jourdanis had previously done, that wood, like metals, can restore sensibility, and that, just as there exist active and inactive metals, there exist also woods with variable action, so that, alongside of *metallotherapy*, we have *xylotherapy*.

The method invented by Burq, and called *Burquism*, gave rise to numerous experiments which were not limited to the school of Salpêtrière. In Germany, Westphal, Eulenburg, Mader, Ost; in Italy, Maragliano, Sepelli, Sciamanna, Parona; in England and America, Thompson, Hughes Bennett, Tuke, Donkin, Sigerson, Beard, Gradle, and Hammond, repeated the experiments of Burq, and to-day we have documents sufficiently complete, and sufficiently numerous to enable us to appreciate this method at its just value.[1]

First, how are these metallic applications made? In a very simple manner. All that you have to do, is to apply to the skin of your patient certain metallic plates as directed by Burq, or what is much more handy, pieces of money, and to watch the phenomena that occur after this application, which may have a variable duration and extent; thus, for example, you can make bracelets or girdles of these coins, to be worn for a time around the diseased part. We utilize in same way the disks of wood or of dried collodion; as for magnets, you should use large ones, of considerable power, and a weight of at least twenty pounds.

Internal metallotherapy may be tried; *i. e.*, having once recognized the active metal, you may give some pharmaceutical compound containing a salt of the metal in question. On this principle, chloride of gold has been given in the dose of one to two centigrammes a day, nitrate of silver in the dose of one centigramme, the salts of zinc, and especially oxide of zinc, in the dose of twenty to thirty centigrammes, the salts of copper, the salts of iron, etc.

What are you to think of metallotherapy? Are there certain genuine facts at the basis of this medication, or is it a species of dupery? After the report of Dumontpallier to the Society of Biology, medical men here in France and abroad were divided into two parties, one party maintaining that metalloscopy had no serious basis, and that a certain effect wrought on the imagination of hysterical patients, "expectant attention," as it was called, explained all the phenomena observed; others, on the contrary, maintained the positive remedial power of the metallic applications, apart from any "moral" effect.

To-day, gentlemen, unless we except a few obstinate individuals whom nothing can convince, everybody seems to be agreed that there do exist æsthesiogenous substances which restore or transfer sensibility, or cause to disappear certain nervous troubles, not only in the case of neuropathic persons, but also in certain lesions of the nervous system. But while admitting the truth of the facts adduced by Burq, it must be borne in mind that from the exclusive point of view of therapeutics, this method has not realized all that has been expected of it. Yes, the application of metals to the cutaneous surface has sometimes caused sensory troubles to disappear; it has even cured certain contractures, but these are exceptional facts, and the results obtained are temporary. In short, metallotherapy merits a very humble and secondary place in the treatment of hysteria.

I have experimented much with metallotherapy in my hospital service. I have observed facts very curious, very strange, the physiological explanation of which seems to me, at present, impossible to give; but my hysterical patients have not derived from this method any definite or lasting benefit, and they generally go away in about the same condition as when they entered. I add that there is a certain number of anæsthetic hysterical patients on whom metallotherapy has no effect, especially when the loss of sensibility is general. At the same time I admit that there is between the convulsive manifestations of hysteria and disturbances of cutaneous sensibility a very intimate correlation, and when you cause the latter to disappear you often cure the former. We have, then, every interest, from a therapeutic standpoint, in restoring sensibility to the skin, and as metallotherapy is one of the means for attaining this end, in spite of the temporary and often uncertain results which are obtained, it is not best to abandon this mode of treatment, which is attended with no danger, and enables us, in certain cases, to obtain alleviation, if not permanent cure.

I have now finished the general treatment of hysteria, and come to the second part of my subject, the treatment of the attack. When a hysterical subject has an attack, you ought instantly to place her on a small bed or cot convenient for passing around; you should remove all tight clothing and every thing which can cause constriction, and then proceed to employ the various means in repute for putting an end to the paroxysm. Formerly they were in the habit of pouring or dashing cold water on the face of the patient. Cruveilhier, reviving an ancient practice, made the patient swallow large gulps of cold water, but lately we have found a quicker and surer method, that of compression of the ovary.

---

The ancients, who attributed to the uterus a preponderating *rôle* in the convulsive manifestations of hysteria, had already proposed various manœuvres, which consisted in compressing the womb, in putting in the vagina odorous substances for the purpose of acting directly on the womb, or in various measures for ridding the womb of purulent humors which it was supposed to contain (such even as titillation of the external genitals and neck of the womb, as recommended by Galen, Forestus, and Ambroise Paré). Areteus, Aetius, Sauvages, Astruc, and others dwell long on the advantages of various procedures; you know even that external compression is of vulgar usage, and you often see persons make pressure and even *sit* upon the belly of patients to arrest convulsive seizures. But this practice has been reduced to method since the labors of the Salpêtrière, which have shown us that one of the most frequent hysterogenous points is the ovarian region, and that it suffices to compress this region, either on the left or on the right side, to bring on an attack or to cause one to disappear.

This is the way to practise compression: the patient being placed on a hard, low bed, the physician, standing by her side, plunges the closed fist perpendicularly into the sensitive ovarian region. It is necessary at first to employ considerable force to overcome the contraction of the abdominal muscles, but once this obstacle is overcome, the hand penetrates the iliac fossa, and the spasms cease if the pressure be continued for a certain time.

Certain apparatuses have been constructed, called *compressors of the ovary*, models of which I now show you, and the most simple of which is that of Ferrè, which consists in a hernia truss, terminated by a conical pad, which is applied over the sensitive ovary. This apparatus, they say, will prevent the recurrence of a convulsive attack; I avow that I have never made use of these compressors, and therefore know nothing about them. Surgeons have even gone further, they have proposed ablation of the ovaries, and we have seen Battey and Peaslee perform this spaying operation in cases of hystero-epilepsy.[1]

Unhappily, not all hysterical females have ovarian troubles, and in such cases the method of compression is not applicable; you can then advantageously have recourse to electricity.

Vigouroux and Richer have shown that galvanic currents, one of the reophores being applied over the front, and the other over some other part of the body, diminish the duration of attacks of hysteria; moreover, if you suddenly reverse the direction of the currents, which is easily done with the commutators of Trouvé and Gaiffe, the attack ceases immediately. You must not exceed six to ten milliampères, for if you do, you will determine severe head-troubles.

In fine, inhalations have been proposed of odorous substances; the number of these is considerable, and the ingredients very strange, from deer's horns and goat's feet, to the odors of candle snuff, of the hairs of men and of animals, and the feathers of partridges and woodcocks; the ordinary perfumes, benzoin, musk, ambergris, etc., have all been advised. To-day we discard all these things, and recognize but a very few medicinal substances, whose inhalation has a beneficial effect on hysteria; these are ether, chloroform, and especially nitrite of amyl. Ether and chloroform may render you some service. I have not, however, been very successful with these anæsthetics. The attacks are prolonged, and they are almost sure to reappear when the anæsthetic sleep has passed off. Nitrite of amyl, with which Bourneville has made so many experiments in hysteria, certainly diminishes the intensity and the frequency of the convulsive paroxysms. You must not, however, resort to it, except during the attacks, for at other times it may determine convulsive seizures. When giving the nitrite of amyl, you pour five to ten drops on a handkerchief, and cause the patient to inhale them.

I shall finish this lecture by giving you, with as much brevity as possible, some indications respecting the treatment of certain manifestations of hysteria. The contractures are the most rebellious of symptoms in hysteria, and nothing is more painful than to see young women afflicted with various contractures, which make life a torture. These contractures appear suddenly after an attack, and may disappear as suddenly after another attack. This is an occurrence which is witnessed in all the manifestations of hysteria, and you have seen a fine illustration of it recently in our wards. I refer to that young hysterical girl who entered the hospital for gastric troubles, and was suddenly taken with contractures, which disappeared after a convulsive attack, which we induced by chloroform, given to anæsthesia. This is then a means of cure which you can employ in hysteric manifestations of every kind.

Electricity, metallotherapy, and cold douches have sometimes caused these contractures to disappear; in other cases they have resisted every kind of treatment, and have persisted for months and even for years. But whatever may be their intensity, they disappear momentarily under the influence of anæsthesia, when carried to completeness, or of energetic compression of the contractured member.

By the side of these contractures we must place paralysis, which appears and disappears with extreme rapidity. This paralysis, which often affects the inferior members, presents this curious peculiarity that it is not always accompanied by trophic disturbances, and you will sometimes see hysterical paraplegics recover in an instant the integrity of their motor functions. It is here that electricity and hydrotherapy may give unlooked for curative results.

As for the troubles of sensibility, I will not repeat what I said while treating of the neuralgias, and I will only say a word or two about anæsthesia. This is, as you know, a disorder almost constant in hysterical women, but one which gives them so little trouble, that a patient whom you observe for the first time will hardly call your attention to this loss of sensibility. I have seen patients presenting the strangest disorders of sensibility. I was the first to observe what I have described as *autographic women*,[1] and always it was

---

[1] To Battey is due the chief credit of this operation, now known as Battey's operation. There are on record three cases, at least, where ablation of the ovaries resulted in permanent cure of hystero-epilepsy, recurring at the menstrual period; those of Battey, Peaslee, and Braun-Ferwald. Vide Battey, Atlanta Med. and Surg. Journal, September, 1872, and American Practitioner, October, 1875. Also, Peaslee, Transactions of the Amer. Gynecol. Soc., p. 340, 1876. Vide Hegar, Die Castration der Frauen, etc., 1878, pp. 13[illegible] 138.

[1] Dujardin-Beaumetz reported to the Societé des Hôpitaux, at their meeting on the 11th of July, 1879, the first case of an autographic woman. In this patient it sufficed to trace on the skin characters or lines, to see developed at the end of a few minutes a salient gyrus, corresponding very exactly to the tracings, which remained for some time, and which, at first limited and strongly defined, spread more and more, to be effaced at the end of four or five hours. The characters so traced were sufficiently prominent so that a wet-proof could be taken of them, as was done for the museum of the Hôpital St. Louis.

Since the communication of Dujardin-Beaumetz the number of autographic women has considerably increased, and this same modification of the vaso-motors has been found, not only in hysterical persons, but also in men and women free from all nervous disease. This symptom then is an urticaria, limited to the point of the skin on which the markings are made. Dujardinthe attentive examination of the patient, and never her declarations, which enabled me to detect these disorders.

At the same time the troubles of sensibility are important from the point of view of treatment, because when they disappear it may be affirmed that the patient will have no more attacks of hysteria. There exists, as I stated before, an intimate relation between the troubles of cutaneous sensibility and the convulsive phenomena. Metallotherapy, static electricity, the application of magnets, in short, all æsthesiogenous substances, may restore this sensibility, but generally this restoration is momentary.

Troubles of the special senses have been noted, and especially of sight. Charcot has pointed out the alterations of vision in hysterical patients, and I have myself observed, with Dr. Abadie, a very curious case of sudden amaurosis in a hysterical female, and which was speedily cured by the metallic applications.[1]

Gastric hysteria is one of the most formidable phases of this neurosis, for it interrupts nutrition, and eventually brings about such disorders as even to cause death. By the term gastric hysteria is understood all the gastric and intestinal disturbances which are observed in hysterical patients, from anorexia to incoercible vomiting. These vomitings may occur under two circumstances; either they succeed to that strange anuria, described by Charcot,[2] or else they come on without any antecedents sufficient to account for them. In the first class of cases you ought to respect these vomitings, as they are uræmic; in the second you ought to endeavor to arrest them. To the therapeutic rules which I gave you when speaking of the treatment of vomiting, I now add artificial alimentation [gavage] and electricity. Forced feeding has given me excellent results in certain cases, when used at the onset of the attacks. Ballet has observed similar facts in the service of Charcot, and you will find in the excellent thesis of my pupil Deniau a certain number of observations of a like kind, cases occurring in my hospital service. At the same time, if you expect success from "gavage," you must begin the treatment at a period not far removed from the inception of the gastric troubles, for, as Débove has judiciously remarked, these vomitings, when they have lasted a long time, produce such an enfeeblement of the organism that all medical intervention is well-nigh useless.

Apostoli has proposed to galvanize the pneumogastric during digestion, in order to prevent these vomitings. He requires the patient to take food; then immediately afterward he places the positive pole over the pneumogastric nerve on the right side, in the region of the neck, while the negative pole is held in the hand; then he passes a current of variable intensity, according as the nausea is more or less frequent. I have, by this means, employed in my service, seen digestion performed without rejection of the matters of the stomach. I shall not enlarge upon this therapeutic measure, which I fully treated of when lecturing on diseases of the stomach.

Such are the considerations which I wished to present respecting the treatment of hysteria. The therapeutic indications which I have furnished are far from being complete; at the same time I think them sufficient to enable you advantageously to combat the principal manifestations of this neurosis. But do not forget, gentlemen—and with these words I conclude—the complete cure of hysteria is very rare. You will hardly have triumphed over one of the many manifestations of this protean malady before others will make their appearance, and, notwithstanding all your knowledge, and all your energy, you will continually fail in the contest with these nervous troubles, ever renewed, and ever rooted in the depraved and insatiable imagination of the hysterical patient.

ORIGINAL ARTICLES.

ABSCESS OF TONSILS, PHARYNX, AND TONGUE,

WITH DISPLACEMENT OF PALATO-PHARYNGEUS MUSCLE, IMPEDING DEGLUTITION AND SPEECH, WITH NASAL REGURGITATION; OPERATION; RECOVERY.

By FRANCIS L. PARKER, M.D.,
PROFESSOR OF ANATOMY, MEDICAL COLLEGE, STATE OF SOUTH CAROLINA, CHARLESTON.

August 8, 1882, Miss P. F., of Colleton Co., S. C., aged twenty-one, six feet high, weight 136 pounds, consulted me for chronic disease of the throat, resulting from abscesses of tonsils, pharynx, and tongue, with displacement of the left palato-pharyngeus muscle, seriously impeding deglutition from nasal regurgitation, and impairing speech. She belonged to a family remarkable for their height and corresponding weight. Her father is six feet high, and weighs 280 pounds; her mother is rather taller than the average, and of medium size. She is the fourth of a family of ten children, four of whom are grown. The eldest son is six feet nine inches; the second son is six feet eight inches; the third (a daughter) is six feet three inches, and this one is six feet. At nineteen years of age, she weighed 197 pounds.

She gave the following history: In April, 1881, sixteen months ago, she had an attack of acute tonsillitis on the right side, consequent upon exposure to rain and cold in crossing a swamp, an accident having happened to the carriage in which she was travelling. The acute attack was followed by ulceration of the throat, which healed slowly, and from April to August she suffered intensely;

Beaumetz, note sur les troubles vaso-moteurs de la peau observes sur une hysterique, femme autographiqué, Bull. et Mém. de la Soc. Med. des Hôpitaux, t. xvi. 2e Serie, 1879, p. 197.)

[1] Vide Charcot, Troubles de la vision chez les hysteriqués, Progrès Médicale, 1878, p. 37. Bonnefoy, Des troubles de la vision dans l'hysterie (Thèse de Paris, 1874). Baron, Troubles de la vision chez les hysteriqués et les hystero-epileptiques (Thèse de Paris, 1877). Galezowski, Progrès Méd , 1878, p. 39. Dujardin-Beaumetz et Abadie, Hysterical Amaurosis, Amelioration by Metallotherapy and by Magnets; Complete Cure under the Influence of Static Electricity (Progrès Médical, 1879). The following is a brief résumé of this most interesting observation: Mlle. X., age sixteen, went to bed, January 21, with headache; had never before experienced any symptoms of hysteria; the next day, the 22d, she awoke totally blind. Examination of the eye by Abadie did not reveal any alteration of the fundus of the eye. There was loss of cutaneous sensibility on both sides of the body. Three pieces of gold were applied to the left temple, and in half an hour partial vision was restored on that side, but on the right side blindness persisted. Acuity of vision in the left eye, one-tenth. Magnets were applied, which ameliorated the right eye, and the sight of the left eye. February 5, acuity of vision was two-sevenths on the left, and one-fifth on the right. Each application of the magnet, or of metal, induced a state of lethargy; static electricity was then employed, and this completed the cure, and it has been permanent.

deglutition was imperfect, and fluids regurgitated through her nose. In August, she recovered, and was comfortable for about three months.

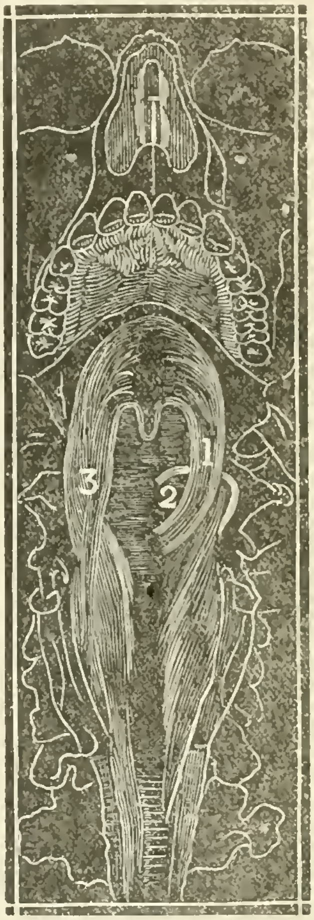
Early in November, an abscess formed in the left tonsil, extending to the side and back of the pharynx; dyspnœa, difficult deglutition, nasal regurgitation, and expectoration of pus and mucus, with cough, continued till May, 1882, when an abscess formed in the substance of the tongue on the left side, and finally opened by two orifices, one at the base of the dorsum of the tongue, the other near the tip on the under surface—both on the left side. After the abscess broke, she could pass her little finger from the anterior to the posterior opening. This was about three weeks in healing.

For six weeks, respiration was difficult owing to her swollen tongue, and at times suffocation was imminent; she could scarcely lie in the recumbent posture; she had constant earache; deglutition was impossible, and for forty-two days she fasted absolutely, and did not swallow anything, solid or fluid —not even water. On recovering sufficiently to be weighed, she weighed 115 pounds, having lost eighty-two pounds during her illness. The joke in the family was, "You are beating Dr. Tanner." Remembering Tanner's furious attack on the August water-melon after his fast, I asked what she took the first time she was able to swallow. She said she drank a pint of custard almost without stopping, and had since lived on custard, milk, and broths, but that the greater part of everything she took regurgitated through her nose. I know that this account of her fasting so long as forty-two days will naturally excite a derisive smile of incredulity; I will refer to it again.

She began to convalesce in the latter part of May, and I saw her first on the 8th of August following (1882). She was brought to my office in a carriage from the depot, and was so reduced and weak she could scarcely walk up the steps; her respiration was short and painful; her breath offensive as she entered the room; her coughing and spitting of mucus and pus incessant; her articulation nasal, and hard to be understood. It was painful to look at her huge, emaciated frame; she looked like a bag of bones in her clothes.

It is common to hear patients say, "They tell me I have a curious looking throat."

This throat *was* "a curious looking throat." Upon examination, there were two large cicatrices on the left side of her tongue as large as a five cent silver piece, one on the under surface near the tip, the other on the dorsum near the base. This half of the tongue was atrophied and smaller than the other, and partly paralyzed. The left tonsil was enlarged, indurated, honey-combed, and studded with ulcerations; the left palato-pharyngeus muscle was dissected up from the walls of the pharynx, and attached simply by its two ends, one to the palate as usual, but the lower end was displaced, and was attached to the middle of the pharyngeal wall, bulging forward like a piece of ribbon, drawing the palate slightly to the right side. A curved probe could be passed behind it, as in the musculi pectinati in the ventricles of the heart. (See figure.)



1. Left palato-pharyngeus muscle, separated from wall of pharynx, and attached by its two ends to palate and the middle of the posterior pharyngeal wall.
2. Probe passing behind palato-pharyngeus muscle.
3. Right palato-pharyngeus muscle—normal.

(Modified after Cohen.)

This formed a sort of pouch, extending downward to the epiglottis, filled with offensive mucopus, which prevented an inspection of the laryngeal opening with the laryngeal mirror.

Upon cleansing the parts, this pouch was rapidly refilled. I failed to get a view of the epiglottis for several days, and when I did, half of it had been destroyed by ulceration, and the borders and upper surface of the remaining portion were ragged, and covered with ulcers.

The right tonsil was enlarged, indurated, and of almost cartilaginous hardness, projecting beyond the half arches, and adherent to both of them.

The whole wall of the pharynx was thickened and ulcerated as far down as the epiglottis. The throat was very irritable, and the examination was difficult, painful, and prolonged.

The condition described as existing in the tongue and throat will, I think, readily explain the regurgitation of fluids in deglutition, the impairment of speech, and the nasal twang of the voice, as well as the constant cough and expectoration of mucus and pus. She said she spat up a pint of "stuff" a day, and from what I witnessed during the consultation, the quantity was scarcely exaggerated. At this visit I induced the patient to swallow water; she did so unwillingly; the greater part of it came out of her nose, and produced painful choking and cough. I also weighed her in the express office below my own (the subsequent weighings were made on the same scales); she weighed 136 pounds. Her weight before her illness, she said, was 197 pounds; afterwards, when convalescence began, it was only 115 pounds—a loss of 82 pounds—so she had recovered about 21 pounds.

Owing to the irritability and ulceration of the throat, little could be done, except to preserve cleanliness, and educate the throat for future manipulation. This was effected by spraying the parts with the following solution:

R.—Sod. carb.,	
Sod. borat., ...	āā dr. 2.
Glycerin, ...	oz. 1.
Liq. sod. chlor., ...	oz. 1.
Aq., ...	oz. 8.

She was provided with a Johnson's Patent Improved Atomizer, with instructions to draw the tongue forward, and spray the pharynx every two or three hours, and to have the throat mopped with the following, after each application of the spray:

R.—Iodin., ...	gr. 12.
Pot. iod., ...	gr. 24.
Glycerin, ...	oz. 4.

She was told to gargle her throat repeatedly with warm water, so as to soften the indurated parts, and to take maltine with quinine, iron, and strychnia. Her diet was to consist principally of milk and custard.

Her aunt, an efficient nurse, carried out these instructions faithfully, and I attended to her once a day at my office.

August 28.—The effect of this treatment was soon apparent. To-day I took the following note: The secretion and expectoration of muco-pus have greatly diminished; it still collects in the pouch, previously described as formed by the displaced palato-pharyngeus muscle; the breath is less offensive; the irritability of the throat has lessened, permitting the free use of instruments without gagging; the induration and ulceration of the pharynx have improved; she swallows more easily, but still has regurgitation through the nose, though with less spasm and cough. Her condition on the whole is far more comfortable, and her strength is slowly improving.

29th.—To-day, assisted by Dr. Davega, of the hospital staff, I operated upon the displaced palato-pharyngeus muscle by dividing its inferior attachment from the middle of the pharynx, and united it to the side of the palato-glossus, by paring the adjoining surfaces of both muscles, and uniting them by three silver sutures. (It was found impracticable to unite it to the pharyngeal wall.) The operation was very tedious.

The effect of cutting this muscle was first to destroy the pouch in which the mucus and pus collected—my chief object; but the palate was drawn further over to the right side by the antagonistic muscle, and the regurgitation through the nose, which had diminished somewhat as the general irritability of the throat had lessened, again increased for several days. I at first apprehended that I had done more harm than good.

Sept. 3.—Union not having taken place, the sutures were removed, and the severed muscle contracted in a few days close up to the palate. To-day I removed the enlarged right tonsil, liberating the half arches, to which it was united by adhesions. The tonsil was of almost cartilaginous hardness, and the bleeding was very free. In washing her mouth with cold water to stop the hemorrhage, she swallowed a small quantity without regurgitation, and quickly remarked, "I can swallow now," and soon afterwards drank a tumblerful of water without regurgitation, for the first time in many months. On the following morning, she ate bread and milk and hominy, and from this time had no further trouble in swallowing ordinary food. She rapidly improved in flesh and strength; her appetite was enormous for weeks. Her weight steadily increased—sometimes as much as five pounds in a week. In four months her weight increased from 136 pounds to 180 pounds, an average of about three pounds a week. The last time I saw her weighed was in March, 1883, and she had reached 192 pounds, five pounds less than her weight (197 pounds) prior to her illness, which began in April, 1881. She was kept under observation till January, 1883, and has since continued to come occasionally for inspection, the treatment previously adopted being continued at home. She has now entirely recovered; the pharynx and tonsils, however, have a rugged appearance, being filled with elevations and depressions, the remains of former ulcerations, and nearly half of the epiglottis is wanting. She speaks distinctly, but with a decided nasal twang.

This case presents peculiarities of interest in an anatomical, physiological, and pathological point of view rarely met with.

I have carefully adhered to the facts as stated to me prior to my seeing the patient, and to the subsequent operations, treatment, and progress of the case, because I know that some of these statements will appear to those who did not see the patient very remarkable.

The dissecting up of the palato-pharyngeus muscle from its attachments, except by its two ends, is unique, but is easily explained by a glance at the throat. When the abscess formed in the left tonsil in November, it burrowed in two directions, to the side and behind the pharynx, under the muscle and mucous membrane, and opening about the middle of the pharynx, and forward under the palato-glossus to the base and side of the tongue, discharging by two orifices, as before mentioned, through the substance of the tongue, resulting in partial atrophy of that side. Its subsequent division and atrophy prove that the act of swallowing can be performed without this muscle, and that, too, without nasal regurgitation.

Nature, as we well know, often supplies her deficiencies by compensatory devices, but here, in such a changed and thickened condition of all the structures of the pharynx, it is difficult to see how the deficiency of this muscle could be supplied. It could not act in conjunction with its antagonist of the opposite side, and there could be no approximation of the posterior half arches; hence, nasal regurgitation in swallowing.

In connection with the regurgitation through the nose, I ascribed it at first, chiefly, to the displaced palato-pharyngeus muscle, but, on dividing this muscle, the difficulty was increased, and I was at first fearful that I had done harm, though its division was necessary to destroy the pouch.

Five days afterwards, when I removed the indurated right tonsil, and liberated the half arches on the right side. regurgitation ceased promptly, showing that the non-contraction of the palato-glossus and palato-pharyngeus of the right side were chiefly the cause of the difficulty. This had entirely escaped my observation.

Remarks.—In regard to the fasting forty-two days and nights, and *without water, too*, I will only say that it was impossible to listen to the plain, modest account of this young woman, of her sufferings, her thirst, and hunger, her fits of suffocation and strangulation, her prayers for death to give her relief, without believing that she was telling what she believed to be true. An examination of her mouth, throat, and larynx confirmed her statement of the repeated abscesses and ulcerations which she said she had had; this was confirmed by her parents, who are reputable persons. There was no hysteria in this case: a woman of nineteen years of age, six feet hight, and weighing 197 pounds, is not likely to have hysteria; there was no publicity given in the neighborhood to "the long fast;" there was no object in deception; "there was *no money in it*." Her sufferings were fearful; she could not disguise them; she wanted to die, and prayed for death; her family would have been relieved by her death. She did not relate all this at first; on the contrary, she was modestly reticent. It was not until she had begun to improve, and her throat was so educated as to permit me to see by the aid of the laryngoscopic mirror the fearful ravages of the disease which she had undergone, that, in answer to my question of astonishment how she had managed to swallow at all, she said, "I know you will not believe me, but nothing passed my lips for forty-two days, not even water." The physician in attendance, who, I know, is an estimable gentleman, was separated by a distance of twenty miles from the patient, and only visited her at long intervals, and expected her death daily. He told me that he could not testify, personally, to the extent or length of "the fast," but that there were weeks together when he believed deglutition impossible from the condition of her throat, involving pain, choking, and strangulation, and that he regarded the patient and her parents as entirely reliable. Her family thought she had cancer of the throat, and that the case was hopeless.

Nearly all cases of long or pretended long fasts have occurred among women of delicate constitution, and are usually associated with some form of hysteria, and accompanied by wonderful accounts of absence of hunger and thirst, with long trances, and after detection it has always been found that the deception was carried out with the connivance of the family.

The world at large, and the medical profession, too, are divided about Dr. Tanner's fast of forty days, two years ago. Probably as many people believe it as there are who do not believe it.

It was said at the time that Tanner lost seventeen pounds by weight, and that, after the fifteenth day, he drank as much water as he wished, which sustained him, or seemed to assist him to a surprising extent. Supposing that Tanner's fast was honestly carried out with the assistance of water after the fifteenth day, and that he did fast forty days with a loss of seventeen pounds, he was a weak, delicate man; eccentric, but possessing a powerful will, with all his faculties, mental and physical; he had an object, and accomplished it, and risked his life foolishly.

Remembering this, suppose that a young healthy woman, six feet high, weighing 197 pounds, in possession of her mental faculties, but physically unable to swallow, suffering intense agony, hunger, and thirst, and wishing for death, says she survived forty-two days without food or drink, with a loss of eighty-two pounds in weight, and after recovery regains her original weight, within five pounds, in four or six months, and that this statement is substantiated by disease of the throat, which appears to have prevented deglutition, and that all this is confirmed by reputable persons, who have no object in conniving at fraud, and nothing to gain by a false statement. Is this possible?

ON THE VALUE OF THE MOIST-SPONGE DRESSING IN JOINT-AMPUTATIONS. A SUCCESSFUL CASE OF AMPUTATION AT THE KNEE.

By GEORGE McCLELLAN, M.D.,
SURGEON TO THE PHILADELPHIA HOSPITAL; LECTURER ON SURGERY, ETC.

Amputation for disease done in the continuity of a limb is so often followed by the necessity of re-amputation that the question of amputation at the contiguity, or joints, presents itself to the mind of the operative surgeon as a subject of weighty consideration.

The impossibility of ascertaining the limit to which a morbific process in a long bone has extended, even after the bone itself has been laid bare to view, and the unvarying teaching of experience which goes to show that when once the medullary substance in a shaft of a long bone is involved, the cell contamination is likely to extend to the articular cartilages, are important factors in deciding upon applying the knife at the joints to free patients from further annoyance and the distress of a subsequent operation.

Statistics, although for the most part of a fancied value in surgery, furnish a favorable view, which might substantiate the above conclusion.

The impression that exposure of an articulation implies extensive suppuration and exhaustive drainage has done much to keep joint-amputation in the background.

I believe that the chief trouble in the management of wounds liable to considerable suppuration is mainly due to the ordinary surgical dressings; and as the *moist sponge*, of which I am a warm advocate, is so simple in its use, and obviates the retention of any discharges within a wound, I shall hope to gain for it a trial at the hands of others by the recital of its satisfactory employment in the following case of *amputation at the knee-joint*, which I performed on the 29th day of April, 1882, at the Philadelphia Hospital:

The patient, Rose Donelly, aged 44 years, had been affected with an epithelial cancer, which sprung from a cicatrix over the tibia and finally involved the bone, so that amputation was done on the previous January 4th, by one of my colleagues, just above the site of the disease. The remaining portion of the tibia afterwards proved to be diseased, and the patient suffered great pain in the stump, on account of which I operated at the knee, by the oval flap method, retaining the patella and avoiding making the lateral incisions too high upon the condyles of the femur, so as not to interfere with the attachment of the femoral fasciæ and muscles. The ligamentum mucosum was also preserved, so that the patella was retained in position between the condyles. After ligaturing the popliteal and sural vessels, the edges of the wound were carefully approximated with silver wire, and a large soft sponge (previously soaked in carbolized water 1–40) was applied directly to the part, and held in position with broad bands of adhesive plaster, extending diametrically across the sponge and along the thigh, so as to exert equable compression upon the deep as well as the superficial structures. The ligatures were brought out at the most convenient points, and their ends embraced in the grasp of the sponge. There was no external or other dressing applied, except that a light roller bandage was run up the thigh to control muscular spasm, and the thigh itself slightly elevated upon a pillow of oakum. This dressing was not disturbed for twenty-four hours, when it was removed, and afterwards reapplied daily. One of two sponges was used alternately, and kept constantly moistened with carbolized water (1 to 40), while the other was soaking in the solution. At each removal, all the discharges were found within the meshes of the sponge, and the appearance of the wound was satisfactory, except upon the fourth day, when it became erysipelatous (from contamination of an outbreak in the ward). This was combated by wetting the sponge with a solution of sulphate of iron (grs. x, aqua ʒj), and the progress of the case was thereafter uninterrupted towards recovery, which was completed with firm cicatrization and entire cessation of discharges on May 20, three weeks from the date of operation. The temperature reached 100° the first night, and 101° on the fourth night, but with the subsidence of the attack of erysipelas, fell to normal, and remained so throughout the rest of the treatment.

The stump is now firm, and well adapted to the use of an artificial limb. No pain whatever is experienced in it. The patella remains between the condyles of the femur, and there is excellent forward motion, due to the preservation of the function of the extensor quadriceps femoris muscle.

Broad and Spruce Sts.,
March, 1883.

MEDICAL PROGRESS.

Ergot as a Preventive of the Aural Troubles Occasioned by Quinine and Salicylate of Soda.—In three cases of acute articular rheumatism, Schilling has observed that the prolonged administration of salicylate of soda in doses of ℈vss–ʒijss a day, causes permanent aural trouble. The membrana tympani was thickened and of a cloudy aspect. A fourth case, which in two successive days had taken single doses of grs. xxx of sulphate of quinine, became subject to roaring in the ears and deafness. This is not an unfrequent effect of quinine or the salicylates administered in large doses, and Schilling proposes to administer ergot with these drugs in order to prevent this vascular paralysis: for example he gives the following: Ergotine grs. xv, salicylate of soda ʒijss, water ℥vj. S.—A large spoonful every hour. Of eighty-seven patients who have taken this prescription, three-fourths have had no aural symptoms, and the same was noticed in nine other patients who took quinine and ergotine in equal parts. This mixture will be equally preventive of the amblyopia which sometimes follows large doses of quinine.—*Progres Méd.*, June 9, 1883.

Verbal Blindness.—Aphasia presents itself under such a variety of forms, and in such complexity of combination, that there can be no more difficult subject in the whole range of neuro-pathology or psychology. We have obviously used the term in its widest sense as synonymous with disorder of every kind of the faculty of employing verbal language. The following case of what M. Küssmaul would term verbal blindness is reported at length, but still with insufficient detail in some noteworthy points, in the *Gazette Médicale de Paris* of June 16th. A man of business, aged thirty-five, was suddenly seized whilst in the hunting-field with right hemiplegia and aphasia. He had been the subject of severe migraine, but with that important exception had enjoyed good health. Consciousness was lost a few minutes after the hemiplegic seizure. At no time was loss or impairment of ordinary sensation detected. Both the paralysis and the loss of speech were on the mend, when one day the patient wished to complete a letter which he had already begun, and found to his astonishment that he was unable to read what he had written but a few days before. Later on it was discovered that an inability to read printed matter also existed. The letter in question when compared with one dated three years back exhibited no special difference. In talking only occasionally did the patient substitute a wrong word. When seen by Charcot, five months after the onset of the seizure, no important defect remained except right lateral hemiopia and the inability to read. The hemiopia had been indicated by the fact that in attempting to play billiards the ball was seen to be but half a sphere. Acuity, however, in the other part of the field of vision was normal, so that the letters could be *seen*, though not read. Loss of memory for a certain number of substantives and proper names, including those of the streets of Paris, existed. He did not venture alone in the city because of the last defect. He could write his name, his address, and even a long letter, without any important errors, but he could not read what he had written. In order to decipher a word he slowly formed each letter of the term with the tip of his right forefinger, and then the ideas furnished by the movements of his fingers came to his aid and controlled the incomplete, insufficient visual impressions. In the phraseology of Dr. Bastian, the defective action of his visual word centres was helped out by the almost simultaneous activity of the *kinæsthetic* word centres. M. Charcot has utilized, from a point of view of treatment, the help afforded by this *muscular sense*. So much progress was made that whilst at the beginning of his reëducation it took one hundred seconds to read one line of print, after sixteen days twenty-seven seconds sufficed to accomplish the same task.—*Lancet*, July 7, 1883.

Papaine.—Papaïne, or vegetable pepsin, is a milky substance extracted from the stems and green fruit of the *Carica papaya*, an indigenous tree of South America, the Indies, and the Molucca Islands. The exudation of the green fruit and the seeds themselves are very efficient vermifuges. But the most valuable property of the tree is the extract, which contains a large proportion of a principle analogous to animal pepsin, which Wurtz and Bouchut call *vegetable pepsin*. This substance rapidly softens and digests muscular fibre. The emanations of the trees produce this effect on flesh, and in countries in which the papaya grows the inhabitants suspend meat which they wish to grow tender in its branches. M. Wurtz, in a report to the Academie des Sciences (Nov. 15, 1880), asserts that papaïne dissolves two thousand times its weight of fibrin, acting with the rapidity and regularity of the best animal pepsin. Dr. Berthaud says that in the laboratory papaïne is constantly used, and numerous facts prove that its action is certain and constant, and its use enables the experimenter to avoid the adulteration so often met with in animal pepsin. Wurtz and Bouchut have observed that all azotized material, as milk, meat, and fibrin, is digested by the papaya juice in a much larger quantity than by the pepsin of the stomach, and it has the advantage over animal pepsin of dissolving azotized matter as well in an acid as in a neutral or alkaline medium. Papaïne has the same indications for administration as animal pepsin. MM. Trouette and Perret, of Paris, have made five preparations of papaïne—syrup, elixir, wine, cachets, and pills—the general effect of which is equally constant, and which may be administered according to the age, temperament, and taste of the individual.—*L'Union Méd.*, June 10, 1883.

Electrical Current in Pemphigus.—De Amicis relates a case in which the pemphigus was localized on the inner surface of the right leg. The nutrition of the part had suffered; there was marked emaciation; muscular contraction kept the limb half flexed; the skin was covered with thick flakes of epidermis colored greenish-yellow; beneath this the surface was either rose or dark red; here and there were blisters and denuded points. Various methods of treatment, both local and constitutional, had been tried without effect, such as arsenic, iron, quinine, continuous warm baths, emplastrum diachyli, ointment of chrysophanic acid, etc. De Amicis prescribed electricity under the form of alternate induced and constant currents. The *seances* lasted about ten minutes. The results exceeded all expectation. After less than twenty-six sittings all new eruption of bullæ had disappeared. Soon the affected limb had regained its former size, the contraction ceased, the skin recovered its natural hue, and the flakes which fell off were replaced by a branny desquamation. The patient unfortunately resolved to leave the hospital before the cure was complete.—*Edinburgh Med. Journ.*, July, 1883.

Salicylate of Bismuth in Typhoid Fever.—Prof. Henri Desplats, after a careful study of the antipyretic action of carbolic acid, salicylic acid, salicylate of soda, and resorcine, has demonstrated that these agents have an influence on the temperature and other elements of fever, whatever may be the nature and cause of the fever (typhoid, puerperal, variola, intermittent fever, erysipelas, rheumatism, pneumonia, etc.); that this action is sure and prompt when these drugs are administered in sufficient quantities; and that it is quick, causing rapid elimination. He then studied the accidents which these agents have been said to produce (collapse, convulsions, albuminuria, melanuria, etc.), and has established that they do not cause pulmonary congestion or renal lesions, and may be administered in albuminuria; that, if administered in too large quantity, they may cause collapse, but this collapse is rare and not dangerous; that in very rare cases, when given in enormous doses, they will cause convulsions, but these have never terminated fatally.

He now gives the results of his experiments with salicylate of bismuth in typhoid fever. He has administered it in twenty cases. It is more readily taken than salicylate of soda, being less soluble, and, therefore, of less pronounced taste. It consists of salicylic acid 2 parts, bismuth 1 part, although it keeps more readily if there is an excess of 3–4 parts in the 100 of salicylic acid. It may be given in unleavened bread or slightly aromatic syrup of acacia, in doses of grs. xv–xxx, though he has given from ℈iv–ʒijss in a day. A little seltzer water may be given immediately after it to enable the stomach to retain it better, if that organ be very irritable. It is always advisable that a more or less considerable quantity of liquid be drunk after each dose. The effects obtained are of two kinds, *immediate* and *remote*.

The *immediate effects* are comparable, when the dose is sufficient, to those produced by carbolic acid, resorcine or salicylate of soda. To observe these, the patient should be closely watched, and the variations of temperature noted. Vulpian's statement that the temperature does not rapidly abate is erroneous, as M. Desplats shows by several cited cases. The immediate effect is never wanting when the dose is sufficient. It produces a less abatement of temperature than carbolic acid, but the sudden rise so often seen after the abatement from carbolic acid, is not observed. Beside the immediate effects, salicylate of bismuth has an incontestable action on the general temperature-curve. As has already been noted by Vulpian, the morning fall of temperature is greater, especially when no salicylate has been administered during the night. Desplats has several times observed that the temperature continued to abate during the forenoon, when the patient had taken no medicine, and thinks it very likely that these late effects are due to absorption of the drug, which is not very soluble. Sometimes, instead of a fall of temperature, he has noticed abundant perspiration coming on during the forenoon, long after the last dose of the salicylate; this seems to confirm the hypothesis of late absorption.

Remote effects.—It is important to know what action the salicylate of bismuth, regularly administered, exercises on the evolution and termination of the disease. Twenty cases are not sufficient from which to draw general conclusions, but they may be of service in drawing conclusions from an additional number of cases. Desplats divides his cases into three groups:

the first includes the cases in which the fever was arrested, in which it may be said that the drug had an abortive action; the second group includes those cases in which the effect was signal, but not so marked; and the third, those cases which were rebellious to treatment, either terminating in death, or seemingly uninfluenced by the drug. Eleven cases are reported in which it had an abortive action. Vulpian has already observed one case in which the fever was arrested on the fifteenth day by salicylate of bismuth. He hesitated to attribute this effect to the drug, as the rose spots were absent. This does not negative the diagnosis of typhoid fever, however, as cases do occur in which the rose spots are absent. Four cases are recorded in which the action of the salicylate was less pronounced; and five cases, all very severe, two recovering, in which there was no apparent effect. In all, twenty cases are recorded. Epistaxis was a rare symptom, and was in no case abundant. Intestinal hemorrhages occurred in two cases, one of which recovered. Delirium was rare, in one case being attributable to the medicine; this was rather subdelirium than true, and there was also deafness. When large doses, ʒij–ʒijss, were given in three or four hours there was, in some cases, a depression of the vital forces, which passed off when the drug was discontinued. The best results were obtained with doses of ℈iv–ʒjs. —*Bulletin Gén. de Thérap.*, June 20, 1883.

Transplantation of Muscle in Man.—Helferich (*Archiv f. klin. Chir.*, Bd. xxviii. p. 562) reports a case in which, as a result of the removal of fibrosarcoma from the arm of a woman aged thirty-six, the whole upper half of the biceps, with the exception of a thin strand at its outer part, was extirpated. Into the cavity which was left he promptly introduced a large fragment of the biceps from the leg of a dog. The cut surfaces were carefully brought together with sutures, as little injury as possible being done to the parts. The transplanted muscle was much more voluminous than the original portion, and was long after the operation distinctly perceptible to the touch. Electric experiments instituted about three months after the operation showed that the biceps reacted perfectly naturally to both kinds of current. The high point of stimulation situated at the place of section of the musculo-cutaneous nerve was, however, absent. The movements at the elbow-joint were almost normal.—*Lancet*, July 7, 1883.

Relations between Ovarian Tumors and the Broad Ligaments.—M. Terrillon has operated on three cases of ovarian tumors which had prolongations extending into the broad ligaments. He has observed that the development of ovarian tumors into the broad ligaments may be (1) anteriorly and posteriorly, and (2) into the concavity of the sacrum. The broad ligament is hypertrophied, contrary to what is seen in the case of parovarian cysts. The prognosis is more grave than in cases of cysts without prolongations. As regards decortication, Péan and Kœberlé are in favor of it; Karl Schrœder prefers to leave a part of the tumor rather than decorticate. If this is done, however, a fatal peritonitis may be set up. Terrillon makes a distinction according as the adhesions are loose or close. If loose, decortication may be practised, and the two folds of the broad ligament are sutured. If the adhesions are fast, decortication is impossible, and in these cases the borders of the cystic cavity are sutured to the edges of the wound; free drainage is established in all the prolongations, so as to completely disinfect the whole wound. According to him, decortication is preferable where practicable.—*Journ. de Méd. de Paris*, July 7, 1883.

Itching as a Symptom of Bright's Disease.—During the course of Bright's disease, itching is experienced unconnected with any cutaneous eruption, and sometimes invading every portion of the integument.

2. This symptom may be described as occurring in three different forms: 1st, as itching, properly so-called; 2d, as horripilation; 3d, as formication.

3. These sensations are a frequent accompaniment of Bright's disease; they are complained of at various periods; they may be felt both at the outset and during the course of the confirmed malady.

4. When met with at the commencement, they rank as an important symptom and one of great semeiological value; they coincide, at this period, with the pollakuria, the cramps, the palpitations, the disorders of hearing, the epistaxis, etc., and may precede the appearance of œdema and albuminuria, thus serving, without any other aid, to place the physician on the right diagnostic track.

5. Coming on at a later period, they merely constitute an additional and conjoint symptom of the disease.

6. The pathology of this phenomenon is as yet based upon hypothesis. It represents a disorder of the sensory sphere, due, probably, to the irritation produced at the terminal extremities of the nerves by refuse material retained in the blood through failure in the eliminative functions of the kidneys.—*Journ. of Cutan. and Vener. Diseases*, July, 1883.

Relations between Locomotor Ataxia and Syphilis.—Dr. F. de Ranse, in concluding a paper on this subject, draws the following conclusions:

1. Progressive locomotor ataxia is primary or secondary. One sometimes observes, in the course of other cerebro-spinal affections, accidental tabetic symptoms of characteristic type, due to propagation of lesions along the external bands of the posterior cords, which cannot be said to constitute progressive ataxia.

2. Pathological anatomy shows that tabetic symptoms of that kind often supervene in the course of cerebro-spinal syphilis. It is admissible, if not demonstrated, that under the influence of this primitive and extrinsic irritation of the posterior cords, and in virtue of a special predisposition, a secondary locomotor ataxia may be developed. But pathological anatomy shows a line of demarcation, between the syphilitic and tabetic processes, which prevents us considering primary sclerosis of the posterior cords as of syphilitic origin, or accepting the doctrine of a primary specific ataxia.

3. These proofs of pathological anatomy are by no means weakened by the statistics produced in favor of the specific character of locomotor ataxia; they are still insufficient, subject to numerous objections, and need further evidence.

4. Nor are these proofs of pathological anatomy weakened, but rather confirmed, by the results of specific medication in locomotor ataxia.

5. The antisyphilitic treatment, incontestably useful in cases of ataxia symptomatic of cerebro-spinal syphilis, and perhaps at the onset of the secondary form, may be positively injurious in the primary form. Hence it should be prescribed with caution in tabetic cases.—*Gazette Méd. de Paris*, April 28, 1883.

Phosphorus in Osteomalacia.—Dr. W. Busch reports two cases of osteo-malacia treated by phosphorus. The first patient was a fairly healthy-looking woman, thirty years of age, in whom the disease appeared a few weeks after childbirth. The objective signs were confined to the bones of the pelvis. This presented the appearance of having been pressed together from the sides. The symphysis projected forward like a beak, while the horizontal rami of the pubes were sharply bent. Walking was impossible, the patient being able only with the greatest difficulty to move from the bed to a chair. Absolute rest in the horizontal position was ordered to be maintained for three months, and Wegner's phosphorus pills were prescribed. After five months' treatment, the patient was able to go up and down stairs without difficulty. At this time she changed her residence and passed from under observation. The second case was that of a woman, fifty years of age, who complained of intense pain in the right arm near the insertion of the deltoid muscle. A diagnosis of ostitis was made and the ordinary measures were prescribed. No improvement was noticed, and after several weeks the patient abandoned the treatment. In about nine months she again came under observation. She was then reduced almost to a skeleton, was absolutely unable to walk, and was greatly deformed. The dorsal spine was kyphotic, while the cervical spine was so strongly lordotic that the head seemed to rest between the shoulders. The thorax was distorted, the femora were bowed, and the pelvis presented the characteristic deformity of osteomalacia. The patient was confined to the bed for seven months, and took Wegner's pills for a year and a half. At the end of this time the bones were firm, and she could go about without complaint. The deformity had not decreased. The following is the formula for Wegner's pills:

℞.—Phosphori, ...	gr. ⅓–ss.
Syr. simpl., ...	f ℥ij.
M. bene et adde	
Pulv. glycyrrh. rad., ...	ʒijss.
Pulv. gummi arab., ...	℈iv.
Gummi tragacanth., ...	℈ij.
Ft. pil. 250.	

Each pill contains about $\frac{1}{650}$ grain of phosphorus. The dose is one pill twice a day, to be gradually increased. Busch does not consider the drug to be of any value in rickets or caries.—*Practitioner*, July, 1883.

Relation between Flexions of the Uterus and Nervous Affections.—Dr. H. T. Byford, in a paper on this subject, read before the Chicago South-side Medico-social Club, draws the following conclusions:

1. There is some direct relation between flexure of the uterus and hysterical symptoms, especially the melancholia.

2. This form of melancholia is not dependent entirely upon occlusion, for in some cases there is neither occlusion nor dysmenorrhœa. I have a case of a primipara, with anteflexion without occlusion, whose life was perfectly miserable from despondency, fainting spells, excessive irritability, and foreboding of trouble, who experienced no relief from tonics, local stimulants, or glycerine plugs, but whose nervous symptoms improved from the first introduction of an elm bougie. Ammoniated tincture of valerian had afforded temporary amelioration.

3. That the peculiar dilating or rather straightening action of the elm affords much relief.

4. That the beneficial action of the slippery elm bougie is not merely one of stimulation, for, in some cases, the symptoms are worse until the stimulation has subsided, as in the case of Mrs. D. and many others. I have known cases in which the bougie increased the local discomforts, and yet caused improvement in the nervous condition after its removal.

5. That congestion in any part of the uterus is not a constant factor, for in the first case cited there was no sign of any congestion.

6. That ovarian irritation is not the cause of this kind of hysteria, for the bougies could not relieve ovarian irritation so promptly, since they have rather an irritating than soothing effect upon the pelvic organs.

7. Dragging of the uterus upon the ovaries through the broad ligaments is not the cause either, for the change produced in the position is scarcely appreciable at first, and not comparable, the change constantly being produced by the filling of the bladder.

8. That the iliac pains accompanying anteflexion are not of ovarian origin.

9. That pessaries do not afford as decided relief to the general nervous symptoms as elm bougies.

10. That cutting operations, which endanger the life or health of the patient, are unjustifiable for stenosis until gradual dilatation of this kind has been tried.—*Weekly Medical Review*, July 14, 1883.

Removal of Carious Portions of the Vertebræ.—Dr. Böckel relates the history of a case in which he removed the carious portion of the bodies of two dorsal vertebræ by means of the sharp spoon, with gratifying results. From his experience in this case and in operations upon the cadaver, the writer concludes that it is not so difficult as is usually supposed to reach the anterior portion of the spinal column. The resection of an inch to an inch and a half of one rib affords room enough for the finger to reach the bodies of the diseased vertebræ. The danger of wounding any of the great vessels lying in front of the spinal column is not so great as it seems, as the pus has already formed a sinus which serves as a guide to the diseased bone. The bodies of the lumbar vertebræ may be reached by an incision made at the outer border of the sacro-lumbalis muscle, as for nephrotomy. The same operation is indicated in gunshot wounds of the vertebral bodies. The difficulty in such cases lies less in the operation itself than in the uncertainty of the diagnosis respecting the location and extent of the injury to the bone.—*Practitioner*, July, 1883.

Unilateral Retinitis Albuminurica in a Patient with but One Kidney, Diseased, on the Same Side.—Yvert reports the following rare case in a Spaniard, æt. 43, who had had most of the subjective and objective symptoms of parenchymatous nephritis, and in whom the right eye remained absolutely intact throughout the entire course of the disease. In the left eye there were the usual yellowish-white masses of exudation in the retina, beneath the vessels in the region of the macula, and between the latter and the disk. There were numerous punctate hemorrhages, and some larger extravasations. Vision was not much affected when the patient first came under observation, but subsequently was almost entirely lost. After he had been under treatment about six weeks, the vision improved almost to the normal standard, and there was a considerable diminution of the retinal exudation. He subsequently, however, grew very much worse, the vision was again nearly lost, and the patient died in about ten weeks from the time that he first came under observation. At the autopsy the right kidney was found to be entirely absent, there being not a trace of kidney, artery, vein, or ureter, though the supra-renal capsule was present in its accustomed place, and was of normal size. The place ordinarily filled by the kidney was occupied by a portion of the right lobe of the liver, enormously hypertrophied. The left kidney was in its normal position, was considerably hypertrophied, and presented the characteristics of the large, white, parenchymatous nephritis.—*New York Medical Journal*, July 14, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, AUGUST 4, 1883.

IN order that our readers may have an intelligent idea of the area and location of the present cholera epidemic, we give, on another page, a very complete map of lower Egypt, showing all the principal towns at which the cholera has appeared. This map is so printed that it can be detached and placed in a position where it will be handy for future reference and study.

CHOLERA AND QUARANTINE.

WE print elsewhere the latest news of the progress of cholera, and our map shows the position of the infected localities. The disease is steadily progressing in Egypt, but as yet there is no evidence that it has reached Europe, for the cases reported in Havre, London, and Wales are evidently only the common sporadic cholera morbus, such as occurs every year.

It may be said, therefore, that the European Governments have had timely warning, and that the result will test the value of maritime quarantine as a means of checking the spread of cholera. It is generally admitted that inland quarantine and sanitary cordons are useless against epidemic cholera, but the value of maritime quarantine is not yet settled, though the prevailing opinion is that it is at all events worth trying. It has failed sometimes, it has apparently succeeded sometimes, and its success or failure appears to have depended very much on whether it was resorted to in time, and was properly enforced. For example, the appearance of cholera in Southampton, in June, 1865, was for a long time inexplicable, and it was not until several years afterward that satisfactory evidence was obtained that it had existed in Alexandria on the first of June, though it was not announced until the 11th, and during this time vessels had been going from Alexandria to Southampton without check.

Let us now consider briefly the European quarantine systems which are being opposed to it. In France these are regulated by the law of 1867, and the same methods are pursued by all the governments of Southern Europe, with minor modifications as to time of detention, etc., so that it may be called the Continental system.

Its essential feature is the detention of a suspected vessel with its passengers, crew, and freight for ten days' observation. The sick are separated from the well—both are removed from the ship. A suspected vessel is one coming from a port at which cholera exists, or one on board which cases of cholera or choleraic diarrhœa have occurred *en route*. Bedding and clothing are disinfected, but, as a rule, merchandise is not. The exceptions are second-hand goods, feathers, skins, and other things of like character. No special directions are given as to cleansing the ship. The quarantine officials have no discretion as to the time during which the well passengers are to be detained for observation; but if the vessel has a regularly commissioned physician, is in good sanitary condition, and has had no cases on board, the ten days' quarantine may be counted as commencing from the date of sailing from the port of departure.

The English system, as provided in a special order of the Local Government Board, dated July 12, 1883, is what is called a system of Sanitary Inspection, the essential feature of which is that there is little or no detention of persons not actually suffering from the disease, even though they may have arrived on an infected ship, and that there is no fixed limit of time for detention of the ship.

The order above referred to provides that, when any customs officer knows or suspects that a ship is infected with cholera, he shall cause it to be moored or anchored in a place to be selected by himself; shall allow no one to leave the ship; and shall at once give notice to the sanitary authority, who must have the ship examined by a medical officer of health, and this examination must be made within twelve hours, or the ship allowed to go free. If the medical officer of health decides that the ship is infected with cholera, he gives a certificate to that effect, whereupon the vessel shall be taken to a place selected for that purpose by the Port sanitary authority, and moored or anchored.

Every person certified by the medical officer of health to be suffering from cholera is to be dealt with by the sanitary authority under its local regulations.

The medical officer of health is to give directions for preventing the spread of infection, which directions must be carried out by the master of the ship. Articles soiled with cholera discharges are to be destroyed, and the clothing and bedding of those suffering from the disease are to be disinfected or destroyed.

Physicians will readily see that this English system affords very little security against the importation of cholera, and that the order has been framed in the interest of commerce rather than that of public health. Under this order the passengers not yet stricken down with the disease, in a ship containing a dozen or more cases of cholera, must be allowed to land and go where they please, although it is almost certain that within a week some of them will have the disease and become centres of infection. Nor is their baggage to be inspected or disinfected.

Too much is left to the discretion of the health officer, for the pressure on such an officer at such a time is enormous.

The defect of the Continental system appears to be an unnecessarily long time of detention, and not sufficient attention to the ship itself.

The quarantine systems of Boston, New York, and Philadelphia are intermediate between the Continental and the English plans; the well are detained a short time for observation, and the ship is emptied and cleansed as soon as possible.

England will take no precautions that will interfere with her commerce unless compelled to by the placing of restrictions on that commerce by other nations, and she is the chief source of danger to this country at the present time, so far as Asiatic cholera is concerned.

THE IMPROVED CÆSAREAN OPERATION.

THE disposition manifested to return to the old method of abdominal delivery in the management of labors in pelves extremely narrow in their measurements, has stimulated suggestions from many prominent quarters, with the object of increasing the safeguards and precautions against the ordinary dangers attendant upon it. These are proposed mainly in reference to the prevention of hemorrhage, the security of the wound of the uterus against gaping, the warding off of septic influences, and the ensuring of the greatest promptitude consistent with the proper performance of the operation. The various recent suggestions in these directions are very admirably set forth in a series of papers just completed by Dr. Garrigues, of New York, in the *American Journal of Obstetrics*.

In connection with these points, it is interesting to notice an operation recently (March 5th) performed in the Maternity of the Woman's Hospital of this city by Dr. Anna E. Broomall, Professor of Obstetrics in the Woman's Medical College. The patient was a negress, aged 22, with a conjugata vera of $2\frac{7}{10}$ inches, and a very exaggerated inclination of the pelvis, which increased the obstruction. She had been twenty-four hours in hard labor before she came into the Hospital, and attempts at delivery had been made by long-continued and vigorous compression and traction with forceps. At the time of the operation by Dr. Broomall, her temperature was 102° and her pulse 180, with offensive discharge of blood and shreds of tissue; but as the fœtal pulse was distinct, and the mother's condition not absolutely hopeless, the Cæsarean operation was adopted, as giving more chance to both lives than any other method. Craniotomy was inadmissible with the active signs of life in the child, and the Porro operation involved too much shock, and, moreover, her intelligent consent to be unsexed was not obtainable in her then condition.

The operation was performed with full antiseptic precautions as to assistants, instruments, and atmosphere. The main important feature was the adoption of the principle of the Müller-Porro operation, viz., the turning out of the uterus from the abdominal cavity, keeping the edges of the incision closely pressed against the uterine wall, and before incising the uterus making constriction of the cervix to prevent hemorrhage. This plan, first suggested by Litzmann, of Kiel, has been carried out heretofore in a few cases only, and without success, by placing a constricting band around the cervix, either a wire loop, or, as urged by Garrigues, an Esmarch rubber tube, tightened up until complete arrest of circulation is effected. Dr. Broomall, however, modified this portion of the operation in having the *cervix grasped by the hand of an assistant* and securely compressed until the uterine wound was closed by sutures. The hand was applied with its palmar surface upon the lower anterior face of the uterus, with the thumb and fingers extended with the commissure looking downward, then slid rapidly down until the soft tissue of the cervix could be grasped in its embrace, the head being gently pressed upward till the cervical tissues were entirely isolated from it. The softness of the cervical walls rendered an efficient grasp quite easy; and the circulation was absolutely controlled, there being apparently not a drachm of blood lost from the incision in the uterus. The placenta was implanted anteriorly and had to be cut through, causing of course the loss of its contained blood.

The advantage of this method of constriction was seen to be immense. First, there is great saving of time, and that too at a period of the operation when every moment tells upon the vitality of the fœtus.

The difficulty of passing a cord or ligature of any kind over and behind the uterine body, carrying it down between the womb and the edges of the incision—which have to be kept closely in contact to prevent the escape of the intestines—and the care necessary to prevent loops of intestine and portions of omentum being carried down and grasped by the ligature, contused and perhaps permanently injured by the rough constriction, constitutes one of the serious delays in the Porro operation; and the manipulation necessitated by it, disturbing the placental circulation, involves great danger to the child. With the manual grasp, the fingers being gently slid around the cervix from in front and kept close to the uterine wall, such precautions are unnecessary, and the whole constriction is done instantaneously. In Dr. Broomall's case, it was less than fifteen minutes from the time the peritoneal cavity was opened until the uterine wound was completely closed, and in ten minutes more the abdominal walls were closed also, making only twenty-five minutes in all that the abdomen was open. Second, a very important gain by this procedure is in the diminished risk from injury of the uterine tissues or the broad ligament and its appendages by their grasp in the soft hand, with its well-regulated and intelligent pressure, in contrast with their constriction by any mere machine. The hand would not be wearied in so short a time, but if it should become so, it could easily be replaced by the other, with scarcely perceptible interval of grasp.

After thorough cleansing of the cavity, the uterine wound was closed by fine silver wire sutures, passed at very short intervals from the internal surface of the uterus outward through the whole thickness of the wall, and returning similarly through the opposite side, so that the middle of the loop, instead of the twist, was upon the peritoneal edge of the wound, thus bringing the peritoneal surfaces closely together with a little inversion of the edge. The wires were cut pretty closely and the ends turned in between the edges of the incision towards the peritoneal surface. This method was continued until the lower end of the wound was so nearly reached that it was no longer practicable, when silk braid carbolized and waxed was substituted.

The condition of the mother previously and at the time of the operation gave but little hope, if any, of her life, but though the case was fatal after thirty-six hours, the autopsy showed complete union of the uterine wound throughout, and the abdominal cavity free from any trace of blood. The uterine surface was free from inflammatory action, but the intestines in the upper part of the abdomen above the uterus, were largely agglutinated by lymph. The child lived thirty-two hours, and was found to have had a large clot beneath the membranes of the brain, with fracture of the right parietal bone from the compression at the pelvic brim early in the labor.

The advantages of this mode of constriction and the facility with which it can be performed, recommend the plan of Dr. Broomall as a very important advance in the improved Cæsarean operation. The objection urged by Carl Braun von Fernwald to the use of the ligature on the ground of the head being sometimes impacted in the brim (a condition certainly extremely rare in a pelvis of two and one-half inches) would not be applicable to the manual constriction, as the hand with its palmar surface could efficiently compress the cervical tissues against the head itself, quietly raising it upward till it had cleared the brim, the cervix being stretched and thus easily and efficiently grasped.

MYOSITIS OSSIFICANS.

AT the Twelfth Congress of the German Surgical Association, KÜMMELL reports a very interesting case of this rare disease, already noticed by Partsch, Uhde, and Langenbeck (of Wiesbaden), and others. The ossification probably began in intra-uterine life, since it was noticed as early as fourteen days after birth, in the spinal deformity and the hampered movement of the arms. At two years of age, numerous fluctuating tumors were noticed on the back, which gradually hardened, and finally became as hard as bone. In some cases, this process went on so rapidly that a soft lump on the boy's head at twelve years of age in two days had already apparently ossified.

Although it was so widespread, but little pain attended the disease, so much so that the boy's school-life began at seven, and had not been interrupted. It began in the soft parts, and gradually extended to the neighboring bones. The facial muscles were apparently free, and fortunately also the muscles of deglutition, though the floor of the mouth was changed into a fibrous mass, which had involved the hyoid bone and the thyroid cartilage. The respiration was abdominal, the thorax deformed, and the pectoral muscles atrophied and ossified, so that the arms could not be abducted. Three weeks later, when one of the sudden onsets of the ossifying process had occurred (and this spasmodic mode of attack is peculiar to the disorder), the heretofore intact biceps suddenly ossified, and the elbow was fixed in right-angled flexion. The back had suffered more than any other part of the body. The lower extremities were but slightly affected, but had begun to suffer of late more than before.

In Partsch's case, the urine was found deficient in the lime-salts, which were reduced to one-tenth of the normal amount, but in Kümmell's no such change had occurred. The faradaic irritability was decidedly lessened.

The etiology of the disease is confessedly very obscure, partly owing to its rarity, partly to the want of post-mortem and microscopic observations, and partly to the absence of thorough clinical investigation. No effort, for instance, seems to have been made to study the state of the blood in any reported cases. It seems not to take its rise from traumatisms, nor from any other assignable cause, but probably to be an enormous exaggeration of a process which slowly proceeds as we grow older. The well-known fact of the loss of suppleness of the muscular system in consequence of the gradual invasion of the muscular bellies by the tendons as youth passes into age, and the ossification of the connective and fibrous tissues at their attachments to bone, may be cited as illustrations. So marked is the former that acrobats must have begun their muscular training in early youth, and have been constantly trained from childhood if it be desired that they shall achieve success.

It is to be hoped that every case will be investigated with most minute care, and reported at length.

CONTUSIONS OF THE BRAIN AND SPINAL CORD.

With an article under this caption in the American Journal of the Medical Sciences for July, 1883, unfortunately comes to an end a series of valuable contributions to the surgery of the central nervous system, by the lamented John A. Lidell. It is a subject which will well repay study by all those who are liable to meet such accidents.

It is largely a plea for the theory of physical lesion of the brain by *contre-coup*. The bent of modern surgical belief is opposed unquestionably to the existence of such lesions in bone, but it seems to be at least possible in the soft parts, although Dr. Lidell does not enter into the physics of the question, but limits his attention to the clinical side of the case. The cases adduced by Dr. Lidell are valuable as illustrating this form of injury.

Moreover, the paper emphasizes the importance of prolonged care and caution after any injury to the skull sufficiently severe to produce nose-bleed, headache, mental disturbances, or other grave cerebral symptoms, though only temporary in duration.

The occurrence of abscess of the brain from mere contusion is also certainly shown to be possible; and, as denoting the more fearless treatment now often successfully pursued, he advocates trephining and incision of the meninges to evacuate the matter otherwise pent up, and sure to do mischief if let alone. It is a heroic remedy, it is true, but it has been so much more successful than that of a fatal expectancy that it should be much more frequently resorted to in the future.

RATIONAL EDUCATION AS TO TEMPERANCE.

The evils of intemperance are seen by physicians more frequently, perhaps, than by any other class of men, if we except the officials in our courts and prisons. Rum is the most fertile source of physical disease and deterioration, to say nothing of its results—wastefulness, crimes, and moral destruction. Syphilis itself in most cases is born of drunkenness.

To combat this gigantic evil, the Woman's Temperance Union has begun at the beginning. They aim not at legal suppression, or license, but at the education of the young in the principles of physiology and hygiene as applied to alcohol, opium, and their congeners. To do this they propose to obtain the enactment of laws in all the States similar to those now in force in Vermont and Michigan, viz., that there shall be in the public schools as one of the regular studies, elementary scientific instruction in "physiology and hygiene, which shall give special prominence to the effects of stimulants and narcotics upon the human system." Public sentiment shall thus be created by public knowledge of the character, extent, and influence of the evil. It is in the school-house that the dram-shop shall find its strongest foe. Give it twenty years, and it will win.

These women mean business, and they go about it in a most business-like way. Their plans for work are as elaborate as those of any strong political party. No prentice hand has sketched them out. They use no invective, no polemics, no sarcasm, no oratory, but hard scientific facts, and well-founded statistics.

And if systematic work will win, they will not lack for it. They have six departments: preventive, educational, evangelistic, social, legal, and one on organization, with numerous subdivisions, such as, on heredity, hygiene, scientific instruction, literature, the press, medical associations, statistics, prisons and police, railroad employés, the army and navy, women, fairs, capital and labor, legislation, the franchise, and work among various nationalities.

Last year, at St. Paul, through their inspiration the American Medical Association passed strong resolutions deprecating "the alarming prevalence and ill-effects of intemperance," bespeaking "conscientious caution" on the part of the profession in prescribing such potent drugs and welcoming "any change in public sentiment that would confine the use of liquors to the uses of science, art, and medicine."

As a public journal, striving for the health of the community, we can strongly commend this action and place ourselves heartily in accord with the calm scientific spirit which seeks to suppress intemperance and vice.

REVIEWS.

Manuel des Injections Sous-cutanées. Par Bourneville, Médecin de Bicétre, et Bricon, Docteur en Médecine. 16mo. pp. xxxvi. 175. Paris: A. Delahaye et E. Lecrosnier, 1883.

Manual of Subcutaneous Injections. By Drs. Bourneville and Bricon. Paris, 1883.

The subject of hypodermatic medication cannot be fully discussed in one hundred and seventy-five sextodecimo pages. There is, however, much more in this book than might be supposed from its size. It opens with a history of hypodermatic medication, descriptive of the various syringes in use (on the Continent, more especially), a table showing the solubility of a number of substances in one hundred parts of water, and a short discussion of the local accidents sometimes occurring in the use of the syringe.

In treating of the substances used hypodermatically, the following excellent plan is systematically observed: First, the name of the drug, and its solubility in the various solvents; second, its physiological effects; and, third, its local effects, under which are given in many places formulæ for the solution and preservation; and, lastly, the therapeutic use is given.

An unusually large number of drugs are treated of as adapted to hypodermatic use. Prominent among these we notice, aloin, cantharides, cedrin, iron, in the form of the dialyzed, pyro-phosphate, citrate, lactate, and peptonate, guachamaca (see The Medical News, April 7, 1883, p. 385), picrotoxine, bromide and iodide of potassium, resorcin, and tayuya.

The book, unfortunately, contains no index; this defect, however, is in some measure compensated for by the fact that the drugs are arranged alphabetically.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, May 7, 1883.

The President, S. D. Gross, M.D., LL.D., D.C.L., in the Chair.

Dr. Samuel Ashhurst reported the following:

UNUSUAL FRACTURE OF THE PATELLA.

On the 16th of August, 1882, I was called to see a little girl about four years old, who had struck her knee with a large glass marble. Upon examination I found an oblique fracture of the left patella, vertical in direction, and apparently extending from within outwards obliquely through to the joint surface of the bone.

The edge of the fragment presented sharp and clearly immediately underneath the skin, so that despite the unusual character of the injury, I was able to convince myself of the accuracy of the description given above. Slight pressure restored the fragment to its proper position, and it was easily kept in place by strips of adhesive plaster. The tenderness in the joint was such that a pasteboard splint was applied to the under surface of the extremity.

As the accident occurred at a watering place and the patient returned home in a few days, I am unable to give its after-history from my own observation, but I learn from Prof. J. H. Brinton that the patient came under his care with a severe attack of synovitis.

Upon looking over the various standard works, I find that while oblique fractures of the patella are referred to, few cases are given. Indeed, I have only been able to find two. *Hamilton on Fractures*, in his first edition, p. 439, mentions a case where a child five years old fell, and presented the same features of injury as in the case I report, excepting that the line of fracture was near the upper and inner margin of the patella, while in mine it was near the upper and outer margin of the bone.

Malgaigne, translated by Packard, p. 626, refers to a case reported by Daniel Turner, in which a piece of the patella in a girl thirteen years old came away from an abscess, and was believed to have been broken off by striking a door.

The cause of the injury in the case I report is also unusual. Particular attention was paid to the matter, but I was unable to elicit any other history than that immediately upon striking her knee the child cried out. Upon examination of the marble of glass, and probably one and three-fourth inch in diameter, there was a slight nick perceptible upon one side, which, however, seemed totally inadequate to cause the injury, and had no appearance of having been itself caused by the force of the blow, the edges being not at all sharp.

The case was the only one of the kind I have ever seen, and seemed sufficiently unusual to be placed upon record.

Dr. Samuel Ashhurst also reported the following case of

REMOVAL OF FOREIGN BODY FROM THE FEMALE BLADDER.

In the month of October, 1882, a married lady, about thirty-five years of age, presented herself at my office and informed me that a portion of an ivory knitting-needle had slipped into her bladder three days previously. The account given of how it happened was of course apocryphal.

As she had very few symptoms, I at first thought she was mistaken, but upon introducing a long bullet-probe a bony substance was felt near the fundus of the bladder. I was able to make out the position of the knitting-needle to be nearly vertical, the lower end apparently resting upon the bas fond. After considerable trouble I succeeded in getting hold of the lower part of the needle with a pair of bullet-forceps, but found much difficulty in getting its end to engage in the urethra. When I at last succeeded in accomplishing this manoeuvre, I found that it constantly impinged against the walls of the canal, but was ultimately able to withdraw it without seriously injuring the mucous membrane. When extracted the cause of the difficulty was evident in the rough sharp edges upon the broken end of the needle which came first. There was some bleeding at the time, and slight vesical irritation for forty-eight hours afterwards, but no further trouble. The fragment of bone needle herewith shown is three and a half inches long and about three-eighths of an inch in diameter.

Dr. F. H. Gross also reported a case of

FOREIGN BODY IN FEMALE BLADDER.

About two years ago he was requested by Dr. Franklin to assist in the removal of a stone from the bladder of an out-patient at the German Hospital. The patient belonged to the working class, and was about fifty-six years of age. She said she had at one time worn a Meigs' ring pessary but had lost it (?) Dr. Franklin dilated the urethra and introduced a narrow pair of forceps, expecting to extract the stone or crush it. The hard body could be felt by the instrument, but could not be grasped. I endeavored to introduce my fingers into the vagina and give assistance in that way, but found the vagina puckered into a mass of folds and ending in a cul-de-sac. The Doctor then introduced his little finger into the urethra and soon astounded me with the announcement that there was a pessary in the bladder. I verified the statement with my own index finger. By pressing downwards the point of my finger came in contact with the inner surface of the ring pessary, which was incrusted and rough from deposits from the urine. By a lateral movement of my finger, the pessary was made to rotate completely around. We were not prepared for such a discovery, and had the patient admitted to the hospital, intending to devise some plan to remove this body from the bladder. Very early the next morning, however, the woman left the hospital, saying she had no time for an operation and must go to work. We have never heard anything of her since. The pessary, which this woman thought she had lost, had evidently produced ulceration and closure of the vagina, and afterwards by ulceration and absorption, through pressure, found its way into the bladder.

Dr. W. G. Porter related a case of

ENLARGED THYROID GLAND; TRACHEOTOMY; DEATH.

Julian N., a Russian, sixty-three years of age, applied for admission to the Presbyterian Hospital, June 13, 1881, with an enlargement of the thyroid gland, which was giving him considerable trouble, and gave the following history: His family history was good, and he had been perfectly well until three years previous to admission, at which time he had noticed a small tumor on the right side of his neck, over the thyroid gland. This had steadily increased in size, and latterly he had suffered from headache, dizziness, noises in the ears, slight difficulty in swallowing, and occasional difficulty in breathing. These symptoms had increased with the enlargement of the tumor, and, obtaining no relief in the Dispensary, he was admitted to the Hospital on the above date, under the care of my colleague, Dr. Allis. On examination, the thyroid gland was found enlarged, and presenting the usual appearance of a goitre. The enlargement occupied the median line and right side of the neck, and had evidently encroached on and displaced the trachea to the left. He now complained of great pain in his head, entire loss of appetite, great prostration, difficulty in swallowing, and constant difficulty in breathing. He was put to bed, and put on a tonic course of treatment, with a most generous diet, on which he rapidly improved, and, refusing all operative treatment, left the hospital July 7, thirty-seven days after admission, greatly relieved.

On September the 16th, he was again admitted, under my care. His condition was very much worse. He was very weak and anæmic; his pulse was rapid, feeble and intermittent; his respiration was very much accelerated, noisy, and difficult; he had great difficulty in swallowing, and his voice was reduced to a whisper. He also had a very troublesome cough, and expectorated great quantities of a muco-purulent matter, which was very fetid. Over the most prominent part of the tumor the skin had sloughed, leaving an irregular ulcer, larger than a silver dollar, the odor from which was almost unbearable. His lungs were carefully examined, but no disease in them could be detected. From the peculiar sound of the respiration, together with the constant expectoration of purulent matter, and the absence of evidence of lung disease, we were led to believe that an abnormal opening existed in the trachea, as the result of the pressure of the enlarged gland.

He stated that his present condition had rapidly developed after the introduction of a needle into the tumor by a surgeon whom he had consulted.

He was again placed on stimulants and tonics, and in a few days began to improve. His pulse became stronger and less rapid, with no intermittence. Expectoration and cough diminished, but the difficulty in breathing and swallowing remained about the same.

On September 21st, five days after his second admission to the hospital, just as I entered the ward, he was suddenly seized with a paroxysm of dyspnœa; he was terribly livid, struggling for breath, and by word and gesture implored us to do something for him. Dr. Allis was present, and we at once decided to open his trachea, in hopes of giving him at least temporary relief.

As the usual position of the incision for opening the trachea was covered by a slough, I determined to make the opening at the side. An incision was at once made along the inner border of the sterno-mastoid muscle, and after a rather deep dissection with knife and director, the trachea was reached and opened. A quantity of blood, mucus, and pus was removed by sponges, and immediately the dyspnœa was relieved. His pulse now rapidly failed, but after the hypodermic administration of whiskey and ammonia, he rallied, and soon felt very comfortable. The depth of the wound was so great that an ordinary tracheotomy-tube was of no use. I therefore cut out a portion of the trachea, and left the wound temporarily open by an ingenious contrivance of bent wire, suggested by Dr. Allis. The patient died, exhausted, three days subsequently, without any return of his suffocative symptoms.

The autopsy showed that an opening existed between the trachea and the sloughing portion of the goitre. The enlargement had mainly involved the right lobe and isthmus of the gland, and the incision which I had made into the trachea for his relief had passed directly through the left lobe of the gland, although the bleeding during the operation was as slight as I have ever seen it in trachectomy.

THE PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday Evening, May 24, 1883.

The President, James Tyson, M.D., in the Chair.

Dr. J. H. Musser presented specimens from a case of

SCIRRHOUS CARCINOMA OF THE RECTUM.

At the autopsy, made thirty-six hours after death by Dr. W. E. Hughes, rigor mortis was well marked, the body greatly emaciated, the skin of an yellow-earth color, and on the right buttock near the gluteal fold the ragged grayish openings of several sinuses, which, we subsequently proved, communicated with a sac behind the rectum. This sac opened into the rectum which at that point was greatly dilated. At the bottom of the dilated pouch in the posterior wall, towards the anus and two and one-half inches therefrom was a hard mass. This mass was the size of a silver dollar, involved two-thirds of the wall, but did not cause occlusion of the gut. The surface was ulcerated. The bowel towards the cæcum was dilated, the mucous membrane congested, and the muscular coat hypertrophied. The remainder of the intestine was normal, and the glands of the mesentery were only slightly enlarged. The liver weighed four and one-half pounds, was very fatty, and in the left lobe a secondary mass larger than a walnut was found. The apex of the left lung was the seat of a small area of catarrhal pneumonia; the base was bound down by rather recent adhesions. Further than this the tissues presented no other change than that due to wasting disease. Microscopical examination revealed the two nodules to be of the nature of a hard cancer.

The patient, a female, thirty-seven years old, had always been a dyspeptic, and of a constipated habit. Her mother and one sister had died of cancer of the stomach, her maternal uncle of the same disease of the liver. I attended Mrs. B., from October 11, 1881, to February 7, 1882. She died in May of the latter year. From the 5th of August previous to my first visit she had been suffering from so-called dysentery—twenty to thirty bloody and mucous stools with tormina and tenesmus. She had grown very feeble and lost much flesh. My notes state abdomen flat, tender all over, especially in the fossæ, but no tumor noticeable. Dysenteric diarrhœa continued, and I may say these discharges kept up during my attendance, at times better and again worse. The mucus was always present; the blood, at times none, again slight or again in large amounts. The appetite was poor and her dyspepsia bad. The debility and emaciation progressed and the appetite became less. In November I detected a hard tumor with apparently a raw surface, two and one-half inches from the anus. During December, she complained of pains in the legs and of severe cramps at night. In January she began to complain of pain in the right hip posteriorly. Local and internal remedies scarcely relieved it and finally the post-rectal abscess discharged. Death from exhaustion ended the career of horrible suffering. I would remark that in all probability the obstinate constipation predisposed to the location of the disease. The constant irritation of the hardened feces would tend to the deposition of the cancerous growth in this locality in a person predisposed to that disease. I have not seen constipation noted as a factor in the etiology of rectal carcinoma, but I think such a view plausible, and that we may infer the practical point—soluble bowels in the cancerous inclined.

Dr. J. H. Musser presented specimens from a case of

SARCOMA OF THE BLADDER.

I am indebted to my friend Dr. Samuel R. Skillern, for whom I made the autopsy, for the privilege of exhibiting this very interesting specimen. At the time of the examination the skin of the body was of the characteristic cachectic hue, the rigor mortis was marked, the emaciation considerable, though not striking, for on section there was a fair amount of fat in the abdominal walls and in the omentum, while the muscles were comparatively large. The abdominal cavity alone was examined. The peritoneum was healthy, the stomach and intestines of a normal appearance. Neither the mesenteric nor any other lymphatic glands were affected. The liver was slightly enlarged and fatty; the spleen normal. The genito-urinary tract was removed intact, the kidneys being severed from their attachments with difficulty on account of being surrounded by fat. Beginning with the kidneys, the left was about half the natural size with thickened adherent capsule. The pelvis was very greatly dilated, the secreting portion reduced to one-third the natural size. The medullary portion was mostly atrophied, the cortical was thin, hard, and pale. The right kidney was larger by one-third than normal, was also cirrhotic, and although its pelvis was dilated, the secreting portion was not atrophied very much. The ureters were very much dilated; averaging the size of the index finger. The bladder was in its normal position, and on opening the calibre was found lessened by one-half, the walls much hypertrophied. At the base of the bladder, in the trigone vesicale, a flat tumor was detected. It measured two inches transversely, and one antero-posteriorly. The base of the tumor was smaller than the upper surface. This surface was irregular, at some places ulcerated, at others covered with phosphatic concretions. The orifices of the ureters were found by hydrostatic means, to open into the tumor, and, hence, were somewhat occluded. The urethral canal was not encroached upon. To the left of the large tumor, were two small secondary masses. Microscopical examination of the kidneys and the tumor: in the former, interstitial and tubular nephritis was found. The tumor was of the histological appearance of a sarcoma. The sections are under the microscope for examination.

The person from whom these specimens were removed, had been a successful minister in charge of a large congregation. He had always been a great mental worker. At the time of his death, he was fifty years old. During his life, his habits were most exemplary. His previous health was good; in his family history no evidence of hereditary disease could be traced.

For the clinical history I am indebted to the various medical gentlemen that attended him.

Prof. Agnew was consulted more than two years prior to death on account of vesical irritation. Six months thereafter he passed blood by the urethra. Careful examination at this time and before, both by the urethra and rectum, failed to detect any tumor or calculus. In a short time the cachectic hue became evident, and with all, the Professor suspected malignant disease. The hemorrhages became more profuse and occurred more frequently. Prof. Tyson was then consulted. He very kindly allows me to extract the following from his notes:

Dr. Tyson said that Mr. S. first came under his observation May 27, 1880, being then forty-seven years old. He stated that he had been annoyed by frequent micturition for about five years, which gradually increased, until at that time he had to rise two or three times each night, but thought it was more frequent during the day than at night. At first he was completely relieved of this symptom during his vacation, which he spent in the woods, and was still much better at such times. He thought Poland water gave him relief, and he felt compelled to use it constantly. There was at this time a burning sensation at the neck of the bladder. The urine contained at this date one-twelfth its bulk of albumen, enough blood corpuscles to give it a "smoke hue," but no casts. On June 22 he again reported, Professor Agnew in the mean time having passed a sound, and detected a slight stricture, which he thought accounted for the symptoms. The patient was instructed to pass a sound for himself, and he thought it gave him great relief, not only diminishing greatly the desire to pass water, but also relieving the sensation at the neck of the bladder.

Dr. Tyson did not see him again until Oct. 30, 1881, when he reported that during the previous year he had been using the bougie at one time as often as five or six times a week, but more frequently every three or four days. He had been very well during this time, gaining ten pounds in his summer vacation, and at that time not urinating more frequently than any one else, although he kept up the use of Poland waters, of which he was using eight tumblers a day for five weeks while at the spring, and when at home five a day. He now mentioned that during the summer he felt an occasional soreness in the region of the bladder when stooping, and noticed also occasional chalky deposits in his urine. At the time of this visit his urine was acid, sp. gr. 1014, and contained one-fifth its bulk of albumen, but no tube-casts. No note of blood was then made.

On Nov. 7th, his urine contained a sediment equal to about $\frac{1}{10}$ to $\frac{1}{12}$ its bulk, which was composed mainly of blood corpuscles. There were a few leucocytes. He continued to visit Dr. Tyson until March 28, 1882.

During much of this time he reported himself improved, there being much less frequent micturition at times, while the uncomfortable sensations at the neck of the bladder were less. The Poland water was discontinued and ordinary drinking-water substituted, with about the same effect in relieving the symptoms. During most of this time he took oil of eucalyptus in doses of from six to ten drops three times a day, we thought at the time with good effect, but the same changes occurred when he was taking nothing. His urine was always albuminous, sometimes containing blood appreciable to the naked eye; once or twice he passed a small clot of blood from the bladder, and on Jan. 7, 1882, a large clot which he compared to a small leech. Two or three times he brought chalky concretions, evidently phosphates, which he had passed. He always thought the bougie relieved him. He was always worse after a hard day's work, as on Monday, after preaching a couple of times Sunday. Benzoic acid and ergot were used with about the same effect. The oil of eucalyptus apparently gave temporary but no permanent advantage.

On March 28th, he reported for the last time, and said that since his previous visit, seven weeks before, he had been very ill, with what seemed to be an attack of great prostration, in which the urine was little altered, except that there was increased phosphatic sediment. More recently, however, there seemed to be always, except for short intervals, more or less blood in the urine. At no time during his appearance did he present a cachectic appearance, nor any other symptoms except those mentioned of intermittent hemorrhage from the bladder and symptoms of vesical irritation, and had not suspected malignant disease of the bladder while he was under his observation, but thought rather there might be a hemorrhoidal condition of the prostatic plexus of vessels.

During the summer and fall of 1882 the general health of S., failed very much while the vesical irritation was quite pronounced. When under Prof. Agnew's care he began to use a sound, and at this time used it daily for its soothing effect. Along with the slight vesical tenesmus he suffered from a little pain at the head of the penis from the very first. During this time and in the winter the hemorrhages continued. The blood was discharged before the urine; sometimes a considerable amount of pure blood, fluid or in clots. The bloody discharges occurred with every urination, or days would pass by with clear discharges.

DR. SKILLERN attended S., from January 9, 1883, until his death in March 13th. From his notes in addition to the above I glean the following facts: The occasion of the first visit to the patient was due to a fit which he had, and the nature of which was not clear, although it was probably a syncopal attack from blood loss. He suddenly became unconscious, and when seen had a pallid face, cold, clammy extremities, a feeble pulse and shallow inspirations. There had been no convulsion, although slight convulsive movements were noticeable. Hypodermic injections of amyl nitrite soon aroused him, although he dozed for an hour afterwards; there is no evidence to prove that this seizure was uræmic. At this time his general condition was very bad. During January it is noted that he used the catheter frequently, on account of a slight difficulty in starting the flow of urine, and that in using it a grating sensation was felt by him; that the paroxysmal hemorrhages continued; that the constant feeling of discomfort at the neck of the bladder and the dysuria grew worse. Micturition occurred every two hours. In addition to the above, in February he had morning nausea and vomiting—generally losing his early meal —becoming more frequent later in the month. The loss of flesh and strength became very evident, as did the cachectic appearance. Two weeks' prior to death he began to complain of renal pain; the twenty-four hours prior the pain were agonizing. He died of exhaustion. It may be noted that the urine was never suppressed, nor was there ever marked vesical pain. Dr. Formad expressed the opinion, from an examination of the urine several weeks before death, that malignant disease of the bladder was present, confirming the opinion of the other gentlemen. His opinion was based on the character of the epithelium in the deposit, being of the appearance of the deep layers of the bladder mucous membrane.

Dr. Agnew kindly informs me, without referring to his notes, that he distinctly recalls four cases of sarcoma of the badder, all in males, and in all, bloody urine was an early and constantly recurring symptom, amounting in one of the cases to very profuse hemorrhages. Pain in one or both hips was also an early symptom. The patients were all over forty years of age.

This interesting note calls attention to the chief facts of these cases, and an especially noteworthy one—the age of the patient. As is well known, sarcoma in other situations generally occurs in early life, this in later life. Then an examination of the relation of the mouth of urethra to the flat tumor, will show how readily a sound could have passed over the tumor, while the base of the bladder being filled, the sound could not engage the mass. The enlarged prostate, was no doubt, deceptive, obscuring the vesical mass when rectal touch was made.

DR. F. P. HENRY exhibited a specimen of

INTRA-THORACIC ANEURISM MARKEDLY SACCULATED, AND INVOLVING THE ARCH AND DESCENDING PORTION OF THE AORTA AS FAR DOWNWARD AS THE LOWER BORDER OF THE SIXTH RIB.

The following notes were taken by Dr. Howard Kelly, the then resident physician, soon after the patient's admission to the Episcopal Hospital:

Dec. 7, 1882.—There is a "distinctly elevated area about two inches in diameter to the left of manubrium, occupying the first and second intercostal spaces and projecting the cartilage of the second rib. This is also the seat of greatest dulness and of strong bruit and expansile movement. Murmurs heard at apex, ensiform cartilage, and second right costal cartilage. Aortic sounds weak and muffled. Pulse in right radial and axillary, strong. In left radial and axillary weak and distinctly delayed. Brachials at elbow visible, sinuous, and atheromatous. Faint bruit in left axillary; none in right. Strong bruit in left carotid; faint in right. Same relation between subclavian arteries. Faint bruit in abdominal aorta. Left pupil always smaller than right."

Under the use of large doses of potassium iodide, there was a decided subsidence of the external tumor; also of the pulsation and bruit. The most troublesome symptom, dyspnœa, was not however materially benefited.

Death occurred on May 13th, through rupture into the right bronchus, and was immediate.

The removal of the aneurism was rendered difficult by the adhesions to neighboring tissues, especially to the sternum and ribs in front. The fifth and sixth dorsal vertebræ were deeply eroded and at the site of these erosions, the aneurismal wall was entirely gone, its place being supplied by two masses of fibrine accurately fitting into the erosions, but unconnected organically with the sac; they merely acted as plugs. The heart was in an advanced state of fatty degeneration and slightly enlarged. The aortic valves were perfectly healthy, but immediately above them were marked atheromatous changes. The opening into the right bronchus was about the size of a three-cent piece.

NEWS ITEMS.

The Cholera Epidemic in Egypt.—The mortality from cholera continues to be large, and the epidemic shows no signs of abatement. The reported mortality for the week ending July 30th, in the principal towns was as follows:

Cairo (7 days), . .	2495	Damietta (2 days), .	16
Gizeh (5 days), . .	281	Menzaleh (1 day), .	3
Chibin (2 days), . .	347	Ismailia (2 days), .	9
Tanta (5 days), . .	148	Zagazig (2 days), .	23
Ziffe (4 days), . . .	73	Alexandria (3 days),	14
Samanhud (1 day), .	7	Mehalla (4 days), .	181
Mahalet (2 days), .	99	Rosetta (2 days), .	18
Mansura (3 days), .	37		

At Cairo the disease is markedly abating. On July 24th the mortality was 558, and on the 30th it had decreased to 275. The mortality on the intermediate days was respectively 422, 311, 277, 322, and 330. At Chibin it decreased from 113 on the 24th to 81 on the 28th; and at Ghizeh from 95 on the 24th to 51 on the 28th.

Most of the large towns in lower Egypt have been attacked, as will be seen by reference to our map.

Lord Hartington, Secretary of War, stated, on July 26th, in the House of Commons that there had been fourteen cases of cholera among the British troops in Egypt, eleven of which proved fatal.

Under date of July 31st, the commander of the British forces at Cairo telegraphs that the general health of the troops is good. He says that the cholera is less virulent in Cairo, and that the cases under treatment are more hopeful.

Forty members of the army hospital corps have been ordered to Egypt.

The government is considering a project for the partial burning of other dangerous quarters of Cairo like Bulak.

An analysis has been made of the water of the Nile, which shows that it is infected with putrid matter to a point above the cataracts.

The Cholera Symptoms.—Dr. Mackie, Consular Physician at Alexandria, forwarded, on July 19th, by telegraph to the *British Medical Journal* (July 21, 1883) the following interesting details concerning the cholera cases:

At Mansura, the early symptoms of cholera are generally simple diarrhœa, some vomiting, with coldness and blueness of the hands, and cramps, variable in character; the abdominal walls are relaxed, and there is suppression of urine. In some severe cases, the temperature was found to be as low as 96.5° Fahr. during the collapse, rising to 102° an hour after death. The shortest illness proves generally fatal in from nine to twelve hours.

The Medical Commission despatched to Damietta report that the symptoms there manifest themselves in coldness and blueness of the extremities, the skin being cold and wrinkled, the facies choleraica well marked. Aphonia is also present, with pulselessness, vomiting, and diarrhœa, with white, watery dejections, sometimes accompanied with mucus. Cramps occur, and the eyes soon become sunken. the pupils dilated, and a blue circle appears around the orbits; the tongue feels cold; there is suppression of urine, and frequent spasmodic contraction of the fingers; sometimes retraction of the belly, and sometimes meteorism. The temperature is lowered. Symptoms often commence suddenly, with headache and fainting; and premonitory diarrhœa is only occasionally noted. The necropsy showed the large intestine to be empty and contracted, feeling like a cord; the small intestines were congested, and filled with whitish liquid, slightly colored by extravasated blood, but no change was found in the glands. The follicles of the stomach were distended with a watery fluid. The bladder was empty; the liver and spleen slightly congested; the kidneys normal; the lungs congested, and the cavities of the heart filled with dark blood. The gall-bladder was distended, the brain congested. The ventricles of the brain contained a quantity of serum, and there was an arborescent appearance of the meninges.

Cholera in Asia Minor.—Two cases of cholera are reported at the Lazaretto at Smyrna, one of which has proved fatal.

Cholera in Russia.—The correspondent of *The London Times* at St. Petersburg says: One or two cases of cholera have been reported in Russia in the last few days. A Charkoff paper reports several cases of what it calls cholerine. Great efforts are being made to purify St. Petersburg. The clergy have held a special service of intercession for the preservation of Russia from the disease.

The report that cholera has appeared at Rostok is officially denied.

Cholera in England. — Sir Charles Dilke, President of the Local Government Board, said in the House of Commons on July 27th, that in the last fortnight there had been three suspicious cases of sickness in England which were declared to be cholera, but it had been ascertained that they were what is known as simple cholera. There is no Asiatic cholera, he said, in England or in Europe. The deaths from simple cholera in England this year, he stated, had not reached the ordinary average; last week the number was only half of the usual average.

Mr. Cross, Under-Secretary for India, stated that 1161 deaths from cholera occurred in the Bombay Presidency during the first week of June.

Lord Carlingford, President of the Council, stated in the House of Lords on the same day that the Government had no intention to enforce quarantine against shipping arriving at English ports, as it was thought impossible to establish an absolute quarantine system. He said medical inspection would be adopted instead.

Isolated cases of supposed cholera have been reported in Wales and in the London docks. The authorities say they know nothing of any death from cholera in the London docks. The officers of the Local Government Board do not believe that isolated cases imply an outbreak of Asiatic cholera. Several deaths occur in London weekly at this season of the year which are classified as cholera, but which are difficult to distinguish from aggravated diarrhœa. There have been several hundred cases of the latter disease weekly this summer, which is in excess of the average.

The Liverpool Town Council having called the attention of the Privy Council to the danger to public health arising from large cargoes of rags received there from Egypt, the Privy Council sent a reply, in which they declined to interfere in the matter. The particular cargo cited in the Town Council's communication as a cargo of Egyptian rags was not intended to be landed at Liverpool, but to be conveyed to New York or Boston. The Town Council decided to apply for power to deal with rag cargoes.

Precautions have been taken at Glasgow to prevent the introduction of cholera.

Cholera at Rio.—The National Board of Health has been informed that during the week ending July 26, there were twenty-four deaths from cholera at Rio de Janeiro.

Action of the French Government.—The Chamber of Deputies has promptly granted a credit of 50,000 francs asked for by the Government, to pay the expenses of the Pasteur Commission, which is to be sent to Egypt to investigate the cholera epidemic.

The following proposition has been submitted to the Municipal Council of Paris: "That the Préfect of the Seine make the necessary provisions for constructing crematory furnaces in each of the three large cemeteries of Paris, to be utilized in case of an epidemic of cholera."

Precautions Against Cholera in America.—The inspection at British ports ordered by the American Consulate so far has shown no case of cholera or contagious disease on vessels sailing from Great Britain for the United States.

The following telegram has been sent to the Collector of Customs at Boston by the Secretary of the Treasury:

Because of the expiration by limitation of the Act of June 2, 1879 (Chap. 11, 21 Stat.), I conceive that Chapter 66, Act of April 29, 1878, is again in force and the regulations by circular dated March 3, 1879, (Dept. No. 34), are again promulgated. A telegram from Liverpool informs me that the steamer Bavarian sailed on Wednesday for Boston, having one hundred and fifty-five bales of Egyptian rags in her cargo. You will enforce the law and regulations against her from the mildest to the severest, as occasion shall demand, reporting from time to time by telegram or letter as you shall find it necessary to proceed from one degree to another of severity.

The Act of June 2, 1879, was intended as a protective measure against the plague, then prevalent in Russia, and the regulations ordered to be promulgated, read as follows:

Until further orders, no vessel from any port of the Black Sea or the Sea of Azof, conveying any rags, furs, skins, hair, feathers, boxed or baled clothing, or bedding, or any similar articles liable to convey infection, nor any vessel from any port of the Mediterranean or Red Seas, having on board such articles coming from Southern Russia, shall enter any port of the United States until such articles shall have been removed from the vessel to open lighters or to some isolated locality and the vessel disinfected and thoroughly ventilated; and the suspected articles shall be disinfected either by chemical agents and exposure to free currents of air or by burning, as shall be determined in each case by the Surgeon-General of the Marine-Hospital Service.

The certificate of the State or Municipal Quarantine Officer of Health may be accepted as satisfactory evidence of compliance with these regulations on the part of the vessel.

The Board of Health of Boston is taking every precaution against the landing there of infected rags and paper stock from the cholera districts. The steamer City of Boston arrived July 27th from Liverpool. On being boarded by the Custom House officers there were found one hundred and fifteen bales of rags, which are now being transferred to quarantine. The steamer Missouri, of the Warren line, arrived the following morning from Liverpool, and it was found that she had over one hundred and fifty bales on board. They were shipped to quarantine. The leading importers of rags in Boston have agreed not to import rags from places in which they might be likely to become infected.

Surgeon-General Hamilton, of the Marine Service, has written to W. H. Pearsall, of Hartford, in regard to a complaint of the rags on a vessel lying at Belle Dock, New Haven, in which he says that, as the vessel has entered the port, it is under the jurisdiction of the Local Health Officer. Dr. Hamilton says that in 1879, when the plague was prevailing in Asia Minor, measures were taken by the Treasury Department to prohibit the introduction of rags until after their fumigation and disinfection. It was then claimed by the paper manufacturers that the rags when carried to the mill were thrown into vats of chloride of lime and there disinfected simultaneously with their unbaling. As it is impossible to fumigate rags while in bale, nothing more was done with them than to give them plenty of air at the time of their removal to lighters. Dr. Hamilton concludes: "If the statement of the paper manufacturers is correct there would appear to be little danger if immediately removed to the mill."

The following notice has been sent to the consignees of vessels and importers by Dr. Smith, Health Officer of the Port of New York:

In view of the fact that cholera is prevailing as an epidemic in Egypt, and at points in the direct line of commercial intercourse with the port of New York, and that rags, one of the most common of the carriers of the germs of infectious and contagious diseases, are brought in considerable quantity to this port from Alexandria, Cairo, and ports on the Mediterranean east of these ports, notice is hereby given that before such cargo is allowed to pass the New York Quarantine, satisfactory evidence must be given that they have been washed and rebaled at ports this side of the infected localities, and where there is no suspicion that the disease prevails. It is believed that this article of commerce is frequently shipped from the ports referred to to European ports, where competition in freights is so considerable as to make it profitable to reship to this port. Consignees or owners of such cargo will be required to furnish satisfactory evidence that rags reshipped from such ports have been cleansed, disinfected, and rebaled at the port of transshipment.

Cholera Precautions taken by the Governments of Europe.

England.—Steamers coming from India via Suez, will not be regarded as suspicious if they have not stopped at suspected ports; the same will hold regarding vessels from Alexandria, in view of the length of the voyage, if no case has appeared on board. The medical officer of health will, as soon as possible after a suspected ship has been certified to be infected with cholera, examine all persons on board of the same; and all persons who shall not be certified by him, shall be permitted to land immediately on their giving their names and the places of their destination.

France.—The Minister of Commerce has ordered vigorous measures to be taken against the introduction of cholera into French ports. Vessels coming into French ports from Malta, Cyprus, the Suez Canal, and other places near the infected district, will be considered as dangerous. If only suspected, they will be quarantined for seven days. If infected they will be quarantined for ten days, and a thorough system of disinfection carried out. The local authorities are vested with power to carry out these and whatever other measures they may think necessary.

Spain.—The Board of Health of Gibraltar has prescribed a quarantine of twenty-one days for vessels coming from the Suez Canal since June 28. One million pesetas (about $200,000) have been appropriated for the necessary precautions against cholera.

Germany.—Vessels coming from Turkey, Asia Minor, Syria, the northern coast of Africa east of Algiers, the Red Sea, and the western coast of Africa as far north as the Straits of Gibraltar arriving in German ports, will be submitted to special surveillance, if they have come from a port where the existence of the plague, cholera, or non-sporadic yellow fever is suspected, or which, during their voyage, have had any communication with the above-named ports. Suspected vessels will be quarantined for six days.

Italy.—The Minister of the Interior has prescribed the following quarantine rules: Ten days for a ship which has made a voyage of more than ten days without any cholera occurring on board; fifteen days for ships having made a shorter journey under the same conditions; twenty days for a ship of which there is any suspicion of the presence of cholera. These measures are applicable to ships coming from Egypt, Tripoli, Malta, Cyprus, and ports situated on the Suez Canal. Importation of rags and old clothes from any of the above places is prohibited. Ships coming from the Austrio-Illyrian and Dalmatian ports are quarantined for five days.

Belgium.—Five days' quarantine for ships coming from India.

Denmark.—All ships coming from Egypt will be quarantined.

Russia.—The same precautions against the importation of cholera have been taken, as in other European countries. Russian subjects of the Mahomedan religion will not be allowed to go on a pilgrimage to Mecca.

Bulgaria.—Turkish merchandise will be quarantined. A sanitary cordon has been placed on the frontiers of Eastern Roumelia and Macedonia.

The History of the Cholera Epidemic.—Dr. J. Mackie, the Consular Physician at Alexandria, has forwarded to the British Government a report concerning the rise and progress of the epidemic, which appears in the *British Medical Journal*, July 21, 1883, and from which we abstract the following. He says:

I regret that, up to the present, I have been unable to obtain precise information with regard to the outbreak of cholera at Damietta, as no attempt at inquiry has as yet been made to endeavor to arrive at a knowledge of its origin or cause. The existence of "suspected cholera" at Damietta was first made known in Alexandria on Saturday, June 23d, with eleven cases for that day; and I believe the first intelligence was conveyed by telegram from private individuals at Damietta.

The suddenness of the outbreak seems to have paralyzed the Egyptian authorities. Their first act was to establish a *cordon sanitaire* to prevent all egress, leaving the unfortunate population of Damietta to die without help, or succor, or chance of escape. For days after the disease broke out, telegrams were received daily, complaining of the total want of doctors, medicines, and disinfectants, etc. In a town of which the population is stated at 35,000, there seems to have been no organized medical or hospital service, no help of any sort for rich or poor—they were shut in by a cordon and left at the mercy of the disease, to die in numbers and propagate cholera. It never occurred to the authorities to endeavor, by an energetic measure, to save the people and stamp out the disease by driving the inhabitants from the infected part of the town, and camping them out in some healthy place, supplied with good food and water; this they are now doing to some extent.

Until a proper inquiry is made into the origin of the outbreak, whether local or imported, any opinion on this point at present must be more or less speculative.

It is a matter of experience that outbreaks of zymotic diseases generally are favored by conditions which certainly have existed in Egypt for some time. Whether these conditions or causes contained the necessary germ or material for the production of cholera, research may or may not with certainty establish.

For some time past, cattle-disease (bovine typhus) has been raging epidemically in the delta of the Nile. It has been matter of current report, and I may say general belief for some time, that many diseased cattle were slaughtered by the fellaheen, and sold in the bazaars of the villages for food. To save the expense and trouble of burying those that died, it was, and is, a common practice to remove the skins, and pitch the carcasses into the Nile or the nearest canal. The Damietta branch of the Nile, especially in its lower part, from Samanhud and Mansura, seems to have been particularly favored in this respect, for the local European press had been receiving for some time information from correspondents at those places that carcasses of animals were constantly floating down the Nile, exhaling a most offensive odor.

The inhabitants, in addition to breathing this poisoned atmosphere, take their water-supply direct from the Nile, which, in addition, is about at its lowest at this season. It is also subject of report and belief here that the natives have been known to drag the carcasses from the river and use them as food. I make this statement with reserve, for although I have heard it repeatedly stated, I am loath to believe it. The heat at the outbreak of the disease, and for some time previously, had been excessive and oppressive, with damp atmosphere.

The uncleanliness of the town of Damietta, like every Egyptian town, is reported to be abominable, and the inhabitants particularly uncleanly in their persons, their food, and their habits.

At the time of the outbreak of the disease, a large fair, at which it is estimated that 10,000 people were collected, was being held at Damietta. The medical commission, before establishing the *cordon sanitaire*, ordered the people collected at the fair to be dispersed. Such are some of the local causes which would be supposed to favor the development of zymotic disease.

Those who hold that the disease can only have originated by importation, pretend that it has been imported from Bombay, and a report has gained a little credence that two Bombay merchants just arrived in Egypt were at Damietta Fair, and that they brought the germs of the disease either by their person or merchandise. I have not been able to trace these two Bombay merchants, or find out if they showed any symptoms of cholera.

Those that hold that the disease has been imported, give as a reason for this opinion, that cholera has never originated spontaneously in Egypt, and that a short time before the outbreak in Egypt cholera had assumed a more severe form in Bombay. The precise manner or means by which it has been imported, has not been stated, except the report, believed by some, of the two Bombay merchants, and others of a similar character; such as, for instance, a fireman ran away from an Indian steamer at Port Said, and made straight for Damietta. Those who believe in importation by these means, forget or are ignorant of the fact that at the time that the two merchants of Bombay must have arrived in Egypt, there was a long quarantine at Egyptian ports in the Red Sea against India, which these gentlemen must have undergone before setting foot in Egypt. There remains for them their own argument, that cholera-germs may have been conveyed by their merchandise, that they may have been lying dormant in the merchandise for an indefinite period, and escaped destruction by the quarantine disinfection.

This, were it likely to be possible, would prove more than anything else the uselessness of quarantine. They forget also, or do not mention, that when our Indian contingent arrived in Egypt last summer cholera was prevailing in Bombay, and no case happened among the troops or camp-followers, nor was imported by the mass of clothes, merchandise, and material of all sorts, which such an equipment must have brought with it. It is further brought forward as argument, that as the precise nature of cholera-germ, or infection, is not known, that some peculiar conditions may be necessary for its development, and that this year, though not last, the necessary conditions existed, and the imported germ gave rise to cholera. Here we come to a combination of an imported and local origin; but, without proofs, which we at present do not possess, I cannot believe that, with a rigorous quarantine, even if a quarantine were necessary against India, it can have been imported to Damietta.

The reason seems very strong in favor of a local origin. When I compare what information we have of this outbreak, with my recollections of the severe epidemics of Asiatic cholera which visited Egypt in 1865, I am inclined to believe that it has had its origin in local causes, and will not spread to any alarming extent. The ten thousand people who were dispersed from Damietta Fair do not seem to have had cholera amongst them, or to have carried cholera with them throughout the length and breadth of Egypt, as they certainly would have done in 1865. At the time of their dispersion the deaths from cholera were already about forty daily, and the type of the disease virulent, recoveries rare, and death occurring in very many cases after from four to ten hours' illness. The disease has now been prevailing for sixteen days, according to our information, and, with the exception of a few cases in Port Said and Tanta, and two of suspected cholera in Alexandria, has been limited to the small district from Damietta to Samanhud.

Another reason for believing that some local cause was at work, is that, at the outbreak of the disease, the daily mortality from general diseases also increased very much. The ordinary mortality of Damietta from general diseases, which is four daily according to sanitary returns, amounted up to fourteen or fifteen daily, as the deaths from cholera reached their daily maximum, and had been increasing for days before cholera was announced as suspected; and now the daily mortality from cholera and general diseases have both considerably diminished, the latter being reduced to about the ordinary rate.

The sanitary arrangements of the country are as bad as they were in 1865; it is but little changed in that respect. In some of the larger towns, Alexandria, Cairo, etc., magnificent blocks of buildings have been erected, streets paved, etc.; but unfortunately, all has been done with the most perfect disregard of the first principles of sanitary science; and Alexandria at present, with its vile system of sewers, house-drains, and house sanitary arrangements, seems constructed expressly to propagate and engender zymotic diseases. Many of the sewers have not been cleaned since they were constructed, and they are so constructed that it is next to impossible to clean them. None of the closets, drains, or sewers are either trapped or ventilated, and the town is full of stinking cesspools. The Europeans and Levantines, especially Syrian house proprietors, surpass the natives even, in the construction of unhealthy houses. An energetic effort to cleanse the town is being made by a combined Consular, Medical, and Mercantile Extraordinary Sanitary Commission, composed of forty-four members, Europeans and natives, under the presidency of the Governor of Alexandria.

This will do some good work in cleansing bazaars, public places, and the exterior of the town; but the house-closets untrapped, communicating with filthy sewers, unventilated, leaking soil-pipes, or rather holes down the centres of walls serving for soil-pipes and allowing extensive leakage, open latrines for servants in the very centre of the kitchens, will still remain to convey infection from family to family, from house to house; and if cholera visits us, it is bound to spread, in spite of all that the Extraordinary Sanitary Commission can do.

The Egyptian Government is, as usual, receiving its share of praise and blame for measures taken or neglected, to stop this epidemic. Many Europeans, medical men and others, who blame them for not stopping the epidemic, praise loudly the institution of the *cordon sanitaire*. Give them a *cordon sanitaire* or quarantine, and they are given a feeling of safety. I believe that the *cordon sanitaire* was the worst means that could have been adopted, I mean as they imposed it. The *cordon* gave a feeling of safety to outsiders, and the inhabitants within were left to die neglected to propagate cholera, while the authorities had a day or two to reflect and make their preparations for the next step. Had they evacuated at once the infected part of the town, and placed a *cordon* to prevent the return of the inhabitants to it, as well as their communication with other villages, I think it might have been stamped out.

YELLOW FEVER AT BALTIMORE.—The British steamship California, from Vera Cruz, arrived off Quarantine at Baltimore on July 27 with four cases of yellow fever on board, and there had been three deaths from the disease during the voyage. The vessel, officers, crew, and cargo were at once isolated at quarantine.

QUARANTINE AT THE CAPES.—A death from yellow fever occurred on the British steamship Andean, in quarantine at Craney Island, Va. Surgeon-General Hamilton, on being informed of this, ordered the sick to be transferred to the Hospital Barge Selden, at Willoughby's Cove opposite the Rip Raps, where the steamer was also ordered to anchor. All persons having had any communication with the vessel were directed to be isolated for ten days, and their clothing fumigated.

The Surgeon-General advised the removal of the infected vessel from Craney Island, because from personal inspection he has become satisfied that it is too near to Norfolk for the safety of that city (being distant about two miles), and experience shows that previous outbreaks of yellow fever at Norfolk have always proceeded from Craney Island, when that point was used for quarantine purposes.

The Secretary of the Treasury telegraphed to the Collector of Customs, at Baltimore: Instruct revenue steamer Ewing to stop foreign vessels from entering the Capes. If any sickness on board, require them to anchor near Ocean View until boarded by a health officer.

Upon the announcement of the location of the hospital barge at Willoughby's Cove, the Norfolk and Portsmouth Cotton Exchange, and the Merchants and Manufacturers' Exchange held meetings and passed resolutions petitioning the Secretary of the Treasury and the Surgeon-General to remove the hospital barge to Lynn Haven Bay, just outside of Cape Henry, and also to order into quarantine at that point all infected vessels that may enter Hampton Roads.

In view of the conflicting statements relative to the best location for the hospital barge Selden, the Secretary of the Treasury invited the health authorities at Newport News, Baltimore, Norfolk, and Richmond to meet Surgeon-General Hamilton, of the Marine-Hospital Service, at Fortress Monroe, to confer with him on the subject.

The Sanitary Commission met at Old Point on July 28, and established the national quarantine for all approaches on Chesapeake Bay and tributaries at Fisherman's Island, on the eastern shore of Virginia, near Cape Charles. The relief barge Selden was at once towed to that point, and all arrangements made for any emergencies which may arise. The English steamship Calfornia, from Vera Cruz, for Baltimore, was ordered at once to the newly established quarantine.

The Board recommends that the barge Selden be relieved as early as practicable by one of the vessels in ordinary now at the Navy Yard, as the barge is not practically seaworthy, and had she been established at Lynn Haven Bay, would have been lost the first gale with probably all on board.

Surgeon-General Hamilton has ordered Surgeon Henry Smith to take charge of the National Quarantine at the Capes.

New Orleans in a Healthy Condition.—President Jones, of the New Orleans Board of Health, telegraphed to Surgeon-General Hamilton, on July 26th, that up to date there has not been even a suspicious case of fever in New Orleans this year, and that the city is in a healthy condition.

Two men, on July 29, escaped in a boat from a vessel undergoing quarantine at the Ship Island Quarantine Station, and made their way to Pass Christian. When the fact became known to President Jones, of the Louisiana Board of Health, he ordered the arrest of the men. They were taken into custody, and turned over to the United States authorities, charged with stealing the boat.

A Case of Yellow Fever at Philadelphia.—A seaman on the brig Julia Blake died of yellow fever on July 25th, at the Lazaretto Station, to which place he had been removed from the vessel. The brig, which was bound from Havana for Philadelphia, loaded with bones in bags, is detained at quarantine, and will be thoroughly fumigated and the cargo removed before being permitted to pass up the river. She will probably be detained at the station for three weeks.

Yellow Fever at Havana.—There were forty-eight deaths from yellow fever in Havana last week. Surgeon-General Hamilton, on July 30th, received a cable dispatch from Havana stating that the City of Merida, from Vera Cruz to New York, left eleven cases of yellow fever at that port. The steamer was disinfected on Saturday.

Quarantine Power of the Government.—The Secretary of the Treasury has been somewhat puzzled as to what to do in view of the approach of infectious diseases by sea. By chapter 66 of the Laws of 1878, the entry of vessels from infected ports was forbidden or restrained, and the Surgeon-General of the Marine-Hospital Service was empowered, under the direction of the Secretary, to make regulations therefor. At that time, the Russian plague was imminent. Regulations were made which directed quarantine isolation of infectious freight, disinfection, ventilation, and even burning thereof if necessary. By an Act in 1879, chapter 11, the National Board of Health was substituted for the Surgeon-General of the Marine-Hospital Service, and the Act of 1878, so far as it gave power to that officer, was repealed. But the Act of 1879, by its own terms, was limited in existence to four years, which term expired in June of this year.

The query in the Secretary's mind was, Did the expiration of the Act of 1879 revive the Act of 1878? The general rule of common law is that the repeal of a repealing act revives the act which the repealing act repealed. The question then arose as to whether the expiration of a repealing act by its own limitation does not do the same. It was suggested by Lord Ellenborough, in the case of Warren against Windle that it does not. In 6 Wharton, page 294, Chief Justice Gibson, of Pennsylvania, criticised that decision, and declared that it does. Judge Hopkinson (Crabbe's Reports) charged a jury that it does not. Bishop, in "Written Laws," page 187, relying on the case in Crabbe, writes that it does not. Hardcastle writes that it depends upon the legislative intention, and cites the cases of Warren against Windle and Rex against Rogers.

In this confusion of the law, Secretary Folger says he has concluded that Congress could not have meant that the beneficial provisions of the Acts of 1878 and 1879, which are almost the same, except in the designation of the officers to execute them, should lapse entirely. He holds that the repeal of the Act of 1878 by the Act of 1879 was but a limited repeal, and that the expiration of the Act of 1879 by its own terms has revived the Act of 1878. He has, therefore, determined that the Surgeon-General of the Marine-Hospital Service may again issue the regulations in question, and that customs officers shall be instructed to carry them out with due discretion and caution in the use of the measure of severity.

Smallpox in New Orleans.—Smallpox appears still to linger in New Orleans. The mortality from it, for the week ending July 21, was twenty-three.

Parkman Professorship of Anatomy in the Harvard Medical School.—Dr. Thomas Dwight has been appointed to the chair of anatomy, the duties of which he has discharged during the past winter on account of the resignation of Dr. Oliver Wendell Holmes. He brings to the position a ripe experience both as a student and teacher of anatomy.

The Louisville Medical News.—We regret to note the retirement from the editorial management of our Louisville contemporary of Dr. L. S. McMurtry, whose able and scholarly contributions to its editorial columns have largely contributed to the excellent reputation which it has enjoyed.

Dr. L. P. Yandell has associated with himself Dr. H. A. Cottell in the editorial management.

The Lehigh Valley Medical Association.—The third annual meeting of this Society will be held at Easton, Pa., on Wednesday, August 15th, under the Presidency of Dr. Traill Green.

An Ethical Symposium.—Messrs. G. P. Putnam's Sons announce a series of papers, from the New-code stand-point, upon Medical Ethics and Etiquette, by Drs. Alfred C. Post, S. Oakley Vanderpoel, William S. Ely, Lewis S. Pilcher, Thomas Hun, William C. Wey, D. B. St. John Roosa, Abraham Jacobi, and Cornelius R. Agnew.

Dr. D. W. Yandell was a member of the Committee of Citizens which escorted the President from Washington to Louisville to attend the opening of the Exposition.

The British Medical Association.—The annual meeting of this Association was held at Liverpool this week, beginning on Tuesday, under the Presidency of Dr. Waters, of Liverpool.

Dr. Austin Flint will read a paper, in the Section of Medicine, on "Early Tapping in Cases of Ascites."

New Brunswick Medical Society.—The third annual meeting of the New Brunswick Medical Society was held in St. John, on Tuesday, July 19th. The following officers were elected for the ensuing year: *President*, E. A. Vail, M.D.; *First Vice-President*, Thomas Walker, M.D.; *Second Vice-President*, E. M. Patterson, M.D.; *Secretary*, G. M. Duncan, M.D.; *Corresponding Secretary*, W. F. Coleman, M.D.; *Treasurer*, Frank A. Nevers, M.D. The next meeting will be held in St. John, on the third Tuesday in July.

Prof. Virchow's Resignation.—Prof. Rudolph Virchow has resigned from the Association of German Physicians. This step was taken an account of the Association having publicly censured him for writing a note of thanks to an apothecary, Brandt, who sent him a box of pilulæ helveticæ (the formula of which is published) during a recent sickness. This note stated that the pills had been beneficial to Prof. Virchow, and Brandt, without his knowledge, published it as a testimonial. Prof. Virchow thinks that the censure was unmerited, and he denies that he gave a testimonial at any time for these or any other pills.

Health of the Queen.—Many exaggerated accounts have been circulated as to the health of Queen Victoria. The *Lancet* states that there is nothing in Her Majesty's condition to justify the slightest alarm or anxiety.

A Corner in Opium.—There is quite a stiff speculative movement in opium in the New York market, on the assumption that the cholera in the East must seriously interfere with the gathering of the crop. There was every prospect that the crop itself would be an abundant one, but the reasoning now is that the pestilence will not leave hands enough to gather it in or to make the necessary preparation for the succeeding crop. As a result of this talk, prices, within the few days past, have been forced up to $3.75 @ $4.00, duty paid, or about fifty cents a pound advance. As yet, however, the speculators have not succeeded in impressing buyers with their views to any considerable extent, and should the pestilence speedily subside they may find themselves in as dubious a position as other speculators who tried to corner the market in former years, on a short crop theory, and that proved to be based upon a miscalculation.

Health in Michigan.—Reports to the State Board of Health, for the week ending July 21, 1883, indicate that cholera infantum, intermittent fever, cerebro-spinal meningitis, and cholera morbus have increased, and that consumption, rheumatism, typho-malarial fever, and influenza have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present, during the week ending July 21, and since, at twenty places, scarlet fever at twelve places, and measles at twenty-three places.

NOTES AND QUERIES.

AN AUTHOR WANTED.

To the Editor of The Medical News.

Sir: Would you be kind enough to give the following verses, Latin and English, an insertion under "Notes and Queries," in the hope that some of your subscribers may inform us who is the author of the Latin?

They are to be found quoted by Drs. John Ring and Benjamin Waterhouse in their respective sketches of the life of Edward Jenner, in honor of the discoverer of vaccination. (See Ring, Treat. on Cow Pox, part ii., Lond., 1803, p. 915, and where Ring cites it as given in the treatise of Dr. De Carro on vaccination, also in appendix to Waterhouse on Kine Pock, part ii., Cambridge, 1801.)

"Te mater omnis, te lachrymabilis
Accurret uxor, ne caducum,
Orba virum, puerosque ploret;
Seu confluentes forte timet notas
Decora virgo—tu faciem eripis
Periclitantem, protegisque,
Delicias juvenum futuras."

"To thee shall weeping wives and mothers fly,
Or see their husbands and their children die:
To thee the virgin trust her lovely face,
Or some rude blemish rifle every grace.
Oh! hard the perils that around her wait,
Oh! shield her beauties from impending fate,
Nor let a cruel pestilence destroy
The hope of youth and pledge of future joy."

Baltimore, July 23, 1883.

THE USE OF THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE.

To the Editor of The Medical News.

Sir: I have heard and read so much concerning the Library of the Surgeon-General's Office that I hope you will pardon the liberty I take in inquiring of you if the library is available to physicians throughout the country; and if books are loaned outside of Washington, I will deem it a great favor if you will inform me how I should make application for their loan.

Yours, very truly,
***, M.D.

Albert Lea, Minn., July 20, 1883.

In answer to the above, we have received the following note from the Librarian of the Surgeon-General's Office:

Library of the Surgeon-General's Office,
U. S. Army,
Washington, D. C., July 25, 1883.

To the Editor of The Medical News.

Sir: In reply to your inquiries, I am directed by the Surgeon-General to state that books are loaned from this library to other libraries which undertake to be responsible for them, and have suitable buildings for their safe preservation.

Books which can be readily replaced, if lost, are also loaned to individuals upon their making a deposit, with the Librarian, of funds sufficient to make good any damage or loss. Books must be transmitted, each way, by express, and not by mail, and the cost of this expressage must be paid by the borrower. The funds deposited with the Librarian are, of course, returned when the books are received back in good condition.

Very respectfully, your obedient servant,

John S. Billings,
Surgeon U. S. Army, Librarian
Surgeon-General's Office.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 23 TO JULY 30, 1883.

Sutherland, Charles, *Colonel and Surgeon, Medical Director, Military Division of the Pacific and Department of California.*—The leave of absence granted by S. O. 64, Headquarters Military Division of the Pacific, June 30, 1883, is extended two months.—*S. O. 168, A. G. O., July* 23, 1883.

Baily, Joseph, *Major and Surgeon.*—Assigned to duty as Post Surgeon at Fort Concho, Texas.—*S. O. 87, Headquarters Department of Texas, July* 19, 1883.

Turril, H. S., *Major and Assistant Surgeon.*—Granted leave of absence for one month, to commence September 1, 1883.—*S. O. 77, Department of the Platte, July* 26, 1883.

Appel, A. H., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for two months, with permission to apply for an extension of one month.—*S. O. 30, Headquarters Military Division of the Atlantic, July* 20, 1883.

ORIGINAL LECTURES.

OSTEOTOMY UPON THE LEFT SUPERIOR MAXILLA FOR THE REMOVAL OF POST-NASAL FIBROUS POLYPUS.

A Clinical Lecture, delivered at the Pennsylvania Hospital,

BY D. HAYES AGNEW, M.D., LL.D.,

PROFESSOR OF SURGERY IN THE UNIVERSITY OF PENNSYLVANIA, AND ONE OF THE SURGEONS TO THE HOSPITAL, ETC.

(Reported by CHARLES BAUM, M.D.)

GENTLEMEN: No doubt some of you will recall this boy as the patient from whom I removed a portion of a post-nasal fibroma, or fibrous polypus, one week ago. The reasons for not completing the extirpation of the growth at that time were the failure to obtain the consent of his parents for more decided measures, and the numerous attachments of the polypus.

The following history has been obtained from the mother of the boy:

Thomas T., æt. 14, of Irish parentage, was born in Tioga Co., Pa. With the exception of a decided phthisical tendency, the family history is negative. The patient has always been healthy, and very active, working at times in the coal mines. Until about seven months ago he was perfectly well, when he began to have slight obstruction to respiration in the left nostril, at the same time beginning to breathe with the mouth open, and to snore at night during sleep. About the same time, unprovoked epistaxis occurred, and has recurred frequently. His sense of smell began to be blunted on the left side, and, contrary to his natural disposition, he grew very drowsy during the early hours of the day. About one month later (six months ago), a pea-sized body was felt in the left nostril, and a choking sensation was experienced while laughing or crying. No dysphagia was experienced with fluids or solids. About four months ago, the vision of the left eye began to grow dim, and the nose became enlarged and disfigured, while all the symptoms increased in severity. About five months ago (January 2, 1883), he was subjected to an unsuccessful attempt to remove the growth, during which there was profuse hemorrhage, and at which time an incision was made in the left ala nasi, resulting in a V-shaped deformity. Such incisions I would advise to be made at the junction of the alæ nasi with the tissues of the face. In two weeks the growth protruded from the left anterior naris, in color and general appearance resembling flesh. To the touch it was firm and resisting, and was not painful. Three unsuccessful attempts at extraction followed within three months, each being accompanied by profuse hemorrhage, and after which the growth advanced more rapidly, and the patient lost flesh and strength.

On the 24th of last month, he was admitted to my wards. He is of ordinary size, slightly pale, with black hair, long eyelashes, and naturally a fair skin. Upon admission, from the left nostril protruded a dense, firm, fleshy growth, about the size of a chestnut, the surface of which was ragged, and covered with mucus and blood-clots. At present, the protruding portion has increased to about twice that size. The left side of the face is bulging, the eye partly closed, caused by the extension of the growth, and giving the peculiar visage known as "frog-face." When a finger is introduced through the mouth, the growth is felt to be attached to the posterior surface of the septum narium, the left pterygoid process of the sphenoid bone, the walls of the pterygo-palatine space, and the basilar process of the occipital bone.

Morbid growths, both benign and malignant, develop in the nasal passages.

The soft, mucous, or gelatinous polypus constitutes a very large proportion of all such growths. The symptoms indicating this variety of growth are a fulness in the nose, a mucous discharge, and inability to respire with freedom, especially during damp or rainy weather. As the growth increases, all the symptoms are aggravated.

The symptoms which accompany fibrous polypus, or nasal fibroma, may not at first differ from those observed in soft polypus; but as the growth advances, the obstruction to respiration becomes constant, there is frequent epistaxis from embarrassed venous circulation; ulcerations occur, furnishing a sanious and purulent discharge, and the health of the patient is apt to suffer.

In the diagnosis of nasal growths, the sight and touch are invaluable aids.

The translucent appearance, gray color, soft, elastic, pulpy consistence, mobility, hygrometric variations, slowness of growth, and indisposition to bleed on pressure are striking characteristics of soft polypus.

The opacity, flesh-like appearance, firmness, and resistance on pressure, more rapid growth, epistaxis, the unaltered condition in variations of the atmosphere, pedunculated form, tendency to produce deformity of the face and nose, and the occurrence before puberty, as a rule, will point to nasal fibroma, or fibrous polypus.

Although sarcoma and carcinoma possess some of the features just mentioned as belonging to fibrous polypus, yet, in the former, the growth is less firm, more rapid in increase, less liable to hemorrhage, with but little tendency to be pedunculated; occurs after twenty years of age, and tends to produce a dyscrasia. In the latter, or carcinoma, the occasional implication of the lymph-glands and the general cachectic appearance of the patient indicate the malignant disease.

Bony and cartilaginous tumors may be distinguished from polypi by their hardness and feel, when touched with a probe.

These fibrous polypi take their origin from the periosteum covering the walls of the nasal and much more frequently the naso-pharyngeal regions.

The treatment of nasal fibromata will interest us most at present. Repeatedly I have succeeded in twisting such a growth from its attachment by grasping it between two fingers, introduced through the mouth of the patient. When situated on the basilar process of the occipital bone, I have passed a chisel along the inferior nasal meatus, and have shaved the polypus from the bone, as practised first by Gross. Various osteoplastic operations have been proposed and executed in order to expose these growths.

After a consultation with my colleagues, Doctors Hunt and Morton, the operation of cutting the superior maxillary bone from all its connections save one or two, which are to serve as a hinge, thus exposing the growth, and enabling the bone to be replaced again, has been determined upon, and the steps of which I will indicate. After dividing the upper lip in the median line, I will carry the incision around the left nostril, and up along the side of the nose to within half an inch of the internal commissure of the eyelids; then will carry it just below the lower border of the orbit, across the malar bone to its zygomatic process. The periosteum will be divided, and the muscles turned back. The tissues of the hard palate will be divided in the median line, and at a right angle to it, at the junction of the soft palate, leaving the latter intact. After extracting the left central incisor, by means of a fine saw and cutting bone-forceps the connections of the bone will be separated, except at the posterior attachment, which is to play the part of a hinge. By turning the superior maxilla back, a full view of the nasal and post-palatine recesses can be obtained. The amount of blood which may be lost, no doubt, will be large; and should the bleeding not cease spontaneously, styptics and the cautery will be employed to arrest it.

Having freely exposed the growth, I find it has invaded, to a greater or less extent, all the irregularities of the nasal and post-palatine regions, and has extended into the left antrum and lachrymal canal. Very firm attachments bind the polypus to the basilar process of the occipital bone, to the left pterygoid process of the sphenoid bone, and to the spheno-maxillary and pterygo-maxillary fissures. No attachment exists to the bones in the nasal cavities. In general outline, the growth resembles a hammer, the head from which the attachments spring being about the size of a walnut, while the handle, corresponding in length to the nasal meatus, is capped by the portion which protruded externally from the anterior naris. In consistence, it is firm and resisting, and has the general appearances of a fleshy mass.

The hemorrhage having been arrested, I will replace the bone, and, in order to retain it in position as accurately as possible, will drill the bones below the orbit, and secure the approximation by means of silver wire. In addition, the palate processes will be retained in proper relation by wire adjusted to the upper incisor teeth.

The patient, as you observe, has suffered somewhat from the shock of the operation. After being removed to the ward, dry warmth will be applied to his body and extremities.

This is the sixth operation of this character and for this cause that I have performed.

Note.—Separation having occurred at the hinge on the ninth day following the operation, the left superior maxillary bone was removed through the mouth.

After the lapse of two months the patient was discharged. During this time no evidence of return of the disease was detected. His general condition was vastly improved, having regained his healthy color and much flesh. The external deformity following the operation was trifling, only a slight depression in the cheek being present. The voice was altered, partaking of the character of the so-called "nasal tone." During deglutition, solids and liquids were prone to escape from the left nostril.

After the expiration of five or six months, when the tissues shall have contracted and hardened sufficiently, a plate with artificial teeth attached will be inserted, which will improve the quality of the voice and most probably effectually overcome the difficulty in deglutition.

ORIGINAL ARTICLES.

THE ALIPTIC ART.[1]

By FREDERICK PETERSON, M.D.,
OF BUFFALO, N. Y.

About three years ago I read in *Epictetus* a sentence which set me at making researches. It was part of a short dialogue which ran this way:

"Well, have you already considered about entrusting the care of your body to any person?"

"Certainly."

"To a man of experience, I suppose, and one acquainted with the *aliptic art?*"

"Without doubt."[2]

It was these few words which set me thinking and reading, and the material which I then collected I have never until now found time to bring into the shape of a paper upon the *aliptic art*—an art now counted among the lost, but destined to very speedy revival.

Connected with the Roman baths,[3] and also practising by themselves among the Greeks and Romans, were certain men known as aliptæ, and it was their profession to anoint and rub the bodies of their patrons. The rubbing we call to-day *massage*, but the important feature of using oil has been neglected. The aliptic art, then, is the rubbing of the body with oil.

We know so little of the actions of most of the drugs we use in our practice, our knowledge is so uncertain, so false, that the wisest now turn their attention chiefly to hygiene and diet, leaving mystical therapeutics to more credulous, perhaps more empirical minds. To be sure, we can relieve pain, but we are always really treating symptoms and seldom are able to get at the cause of the disease, even if we make a correct diagnosis before death. We have much to apply to the relief of the suffering, if we make use of the accumulated knowledge and experience of this age, with regard to the value of sunlight, of fresh air, of certain foods, of exercise—and their proper application requires nowadays great study.

We seek remedies and effects which are tangible, palpable, and not occult. The aliptic art is one of these. It combines exercise with nutrition. Though the ancients may not have known the reason of its beneficial results, they had sufficient experience of its value in the treatment of disease; and something of what old Jewish, Arabian, Greek, and Roman writers have recorded for us with regard to it, I propose now to relate.

Josephus, in speaking of the case of Herod, mentions the use of the oil-bath in the treatment (*Dict. Ant.*, B. 17, chap. vi.). Isaiah alludes to the use of oil as a remedy (I. 6). Dr. Smith, in his *Dictionary of the Bible*, says, "As is the case generally in hot climates, olive oil was used by the Jews for anointing the body, after the bath and before an entertainment. To be deprived of its use was a serious privation, assumed voluntarily in time of mourning and calamity." Strabo says the Egyptians used castor oil for that purpose. With regard to its use in baths by healthy people, I may quote from Becker's *Gallus*, "The daily bath, and previous to it, strong exercise were inseparable in the minds of the Romans from the idea of a regular and healthy mode of life." The Romans were anointed in preparation for the bath and athletic sports. As a rule, after friction with flour, soda, etc., the hot bath, the cold plunge, they underwent frictions with oils or ointments. Hippocrates[1] speaks of inunction as calefacient, moistening, and emollient. Celsus and Haly Abbas recommended inunction before the bath. Galen used oils before and after with rough towels. Oribasius, Galen, Aëtius, Avicenna, and Gentieis Fulginas used a fifth part of heated oil in a water-bath for fevers, convulsions, retention of urine, nervous pains and lassitude. Mengus Faventinas used it as an anodyne. Paulus, in his chapter on preparatory friction, says, "Before gymnastic exercises the body ought to be rubbed moderately, first with towels, and then with oil in the hollows of the naked hands, until it be properly warmed and softened, and its surface have contracted a florid blush, and become distended." Of the oils used, Paulus speaks farther, "Some are moderately heating as oils of lilies, marjoram, iris, and saffron. Some are dessicative and cutting as oils of elaterium and privet. Some are powerfully heating and tonic, as oils of Chian mastic, must and nard. The most tonic is that prepared from wild olives. Some oils are used by women for their fragrance, as the oil of musk." Alexander Aphrodiensis says the object of its use among the ancients before all strong exercises was to soften the parts so they might not easily be ruptured. Horace says of a lazy person, "*cur olivum sanguine viperino cautius vitat.*" (Lib. 1. c. 8.)

[3] *Vide* Celsus on the Alipterium. Stobaeus and Baccius, De Thermis.

Martial describes ceroma used by the aliptæ as a mixture of oil and wax. Thucydides states that the Lacedemonians were the first who rubbed their bodies with oil before wrestling; and Pliny says the custom was introduced into Rome by the Greeks. Athenæus, says Antiochus Epiphanes, supplied the Daphnean wrestlers with oils of saffron and marjoram. Lucian has Solon to say to Anacharsis that oil acts upon the living body as upon leather, softening and making it less liable to rupture. The poets describe the gods as using inunction, as, for instance, Sophocles and Callimachus. So great a necessity was oil to the Romans that the empire supplied it gratuitously in all the public baths according to Lampidius. Now, as to what the ancient physicians thought of the action of inunction, I quote Paulus Ægineta, who says: "Hard friction contracts, and soft relaxes." Hippocrates and Celsus say: "Violent friction hardens the tissues; gentle softens; long-continued diminishes; moderate increases." Galen, Aëtius, Oribasius, Avicenna, and Haly Abbas agree to this verbatim. Averrhœs states that "hard friction lessens obesity; moderate removes emaciation." Democritus, who was something of a wit, remarked that the health is best kept by lubricating inside with honey, and outside with oil. It was the custom to make use of friction and inunction morning and evening. Now, to speak particularly of the diseases in which the aliptic art was used, for in describing an art so nearly lost as this, I must bring in the ancient physicians as being the chief witnesses to its efficacy, let me take the following:

They used locally in gout, rheumatism, and chilblains, hot oil and friction. Rhazes says the common people put a finger with a felon into hot oil. In all superficial pains, friction with oils was made use of. Celsus says Asclepiades trusted almost entirely to gentle inunction in the sleeplessness of fevers. This was also practised by others. Warm hip-baths of oil and water were used in satyriasis and dysmenorrhœa. Friction with a discutient oil was used by Galen and Paulus in forms of jaundice to allay the irritation of the skin. Paulus says in obstruction and contraction of the pores of the skin, anoint bodies with a sweet and thin oil, of moderate heating quality, like oil of dill or black poplars. The Greeks, Romans, and Arabians all unite in the statement that in tetanus there is a remarkably good effect from the use of hot oil-baths and gentle friction. This certainly should appeal to us for trial, who have exhausted all the poisons of the pharmacopœia hopelessly in treating this disease. In all sorts of tremors or chills, whether from old age, debility, cold, wine, or disease, inunction was practised successfully, the oil of chamomile, privet, iris, or wax with pepper, or simple baths of hot oil being used. In asthma, pneumonia, and other chest diseases, external friction with stimulant oils, such as those of dill, rue, and iris, was used advantageously in connection with internal remedies. Paulus recommended rubbing the whole body with hot oil in hemoptysis. Inflamed breasts were treated with friction, and then wool soaked in hot oil placed upon them. In colic and cholera, a friction and hot-oil embrocations were employed. Friction with oil alleviated the pain in passing of renal calculi. Inunction was a favorite in enlargement of the liver, in bilious colic, ascites, anasarca, and tympanites, where, though not curative, they were anodyne. Of alopecia, Paulus says: "I have seen many have their hair reproduced by friction with oil alone." Serapion, Avenzoar, and others used hot or cold oils in the same manner and with great success upon the head in headaches. Paulus and Haly Abbas recommended inunction in the stupor of some of the acute diseases. Friction of the feet was used as a revulsive in all brain diseases, while the head was anointed and rubbed, especially in vertigo, epilepsy, apoplexy, and paralysis. In paralysis, Paulus says, "Our greatest dependence is upon friction." Tepid oil-baths, with gentle friction, were very beneficial in their hands in convulsions. In profuse sweating, they had with oils and friction splendid results.

The oils used were of a styptic nature. Paulus used oils of apples, lentisk, roses, myrtle, or pomegranates; Haly Abbas, Alsaharavius, Avicenna, and Rhazes using the same, all preferring, however, the oil of roses or myrtle. It seems to me this treatment might be tried nowadays before attempting to use poisons like atropia or pilocarpin. For the dry, hot, rough, and disagreeable tongue of fevers, these ancient physicians were accustomed to order rose oil and honey to be rubbed in, and this might often be used nowadays. In smallpox and measles, which no Roman or Greek author mentions, Rhases, the Arabian, the first to describe these diseases, used friction to bring out the eruption, and warm oils to remove the scabs. In syncope, Galen and Paulus give rigid rules, followed by most of their successors of that day, to rub the body first till glowing with a dry linen cloth, and then to apply some relaxing oil. Hard friction was used by them in somnolency, and also in insomnia. Rhazes says he cured himself of sleeplessness, caused by too much study, by inunction of oil of water-lily. In ephemeral fever soft friction with emollient oils was used by all of the physicians of that day. Oil and friction were ordered by them in other fevers, in septicæmia, or as they called it, putrid fever, in hectic, and in all the continued and intermittent fevers. Celsus lays down for the last stringent rules, "*oleum, frictio, vinum.*"

---

[1] V. Sydenham Soc. translations of ancient authors.

Inunction was used not only to diminish obesity, but to remedy emaciation. Hard rubbing with oils of dill, marshmallow, gentian, or wild cucumber, was of greatest use in obesity. Indeed, Avicenna says nothing reduces obesity as much as frequent baths and hard inunction. In emaciation, very gentle friction with some emollient oil is extremely beneficial, the oil being nutritious, and the soft rubbing stimulant to the tissues. For atrophied portions of the body Paulus, Oribasius, Aëtius, Galen, Rhazes, Haly Abbas, and Avicenna recommend first cold effusion, followed by rubbing with towels and hot stimulant oils. Where the skin is dry and parched, friction with stimulant oils, such as those of chamomile, dill, bays, and violets, often produces perspiration.

Celsus renders to Asclepiades the honor of having invented friction. The latter, in his book on "Common Aids," wrote largely concerning it. Celsus, in his chapter on that subject (Book II., cap. 14, tr. by Collier), speaks of inunction as a means of producing sleep. He says friction relieves long-standing headaches, and often reëstablishes use in paralyzed limbs. In collapse he says we can only put our trust in proper friction, which may revive so far as to admit of other measures being taken. The quality of oil as a poor conductor of heat was known to them. Pliny says oil protects both from cold and heat.[1] They took advantage of this useful property of oils. The soldiers under Alexander the Great rubbed their bodies with oil of sesame, according to Quintus Curtius, when crossing the Baltian Mountains. Xenophon (Anab. Lib. 4) tells how his Greeks, exposed to extreme cold, rubbed themselves before their fires with lard, turpentine, and oils of sesame and bitter almonds. The Carthagenians under Hannibal did the same, according to Florus, among the Italian Mountains. That it is equally protective against heat, witness the inunction practised by the races living in the torrid zone. Averrhoes directs friction with oils for persons who suffer when exposed to the sun.

I have brought out this array of historic facts, not so much to make a short story long, as to show how universal the aliptic art was in past ages. Compared with its everyday uses then, it may well now be called a lost art, and one meriting, for many reasons, recovery. Some years ago, under the name *massage*, the French brought the aliptic art again into vogue, taking the word from the Greek *masso*, to knead, and of late years the Swedes and Germans have carried it into something of its ancient repute. At the same time, though now we use the French word *massage*, and speak of those who practice it as *masseurs* and *masseuses*, it cannot truly be said that it has ever fallen into absolute disuse. Here and there, in the history of diseases in past centuries, we find the aliptic art of the Jews, Greeks, Romans, and Arabians present in ghostly form. I quote the following from *Copland's Medical Dictionary* (vol. iii. pt. 3, pp. 227–8): "Many years ago, frictions of the surface with warm olive oil were much recommended by Baldwin[1] and others in the treatment of the plague, with the view of promoting a copious sweat, which seldom failed of supervening. The practice was common in the East from the earliest times. Several experienced writers are much in favor of it, and the evidence is very conclusive as to its diaphoretic operation when employed externally. Mr. Jackson, in his account of the destructive plague in Morocco, in 1799, recommended it to many, both as a preventive and a cure; and he states that in both characters it was eminently successful."

In 1781, Pichler[2] wrote a little book on the use of inunction in various diseases. In 1799, Trinder published a work entitled, *The English Olive Tree; or, a Treatise on the Application of Oil to the Human Body*, which ran through a third edition in 1812. In 1803, Pienitz,[3] a German, wrote a book upon the therapeutic and dietetic uses of friction and inunction. In 1809 appeared a work by Frank,[4] a Frenchman, on the same subject, followed in 1810 by that of Dähne,[5] a German, recommending the rubbing in of oil in scarlet fever.

In 1822, Zavagli,[6] an Italian, wrote a brochure over the successful use of inunction in ascites. In 1844, appeared another book on the efficacy of oil

[6] Zavagli. Della Unzioni Oleose.

in the treatment of the Levantine plague.[1] Schullmann, in 1848,[2] wrote a book with the title, *A Certain Cure of Scarlet Fever by Means of a Method, New and Wholly without Danger.* This method was the inunction of bacon-fat, by means of which the dryness of the skin disappeared, the itching stopped, the circulation of the blood was promoted, and the period of desquamation was modified. "Owing to the fatty covering, the skin is kept moist, and the cuticle prevented from being driven about the room by currents of air, and thus one fertile source of infection is kept closed up." Schullmann published a second volume,[3] in 1853, concerning massage with oil in scarlet fever and measles.

In 1850, Taylor[4] wrote a work on friction with lard and beef-suet, giving cases of cure of typhus, scarlatina, measles, dropsy, nervous diseases, delirium tremens, and hydrocephalus. Then appeared works by Bauer,[5] La Pierre,[6] a history of inunction by Simon,[7] and a volume by Mole[8] on the same subject. The young English athletes are said to use the aliptic art nowadays as did the Greeks and Romans.[9] In the *Lancet*, of January, 1870, is an article on the use of warm-oil baths in the diseases of children, atrophy, bronchitis, convulsions, diarrhœa, fevers, and cachexias, which is summed up in this wise:

1. The skin action is more completely and permanently restored by this treatment.

2. The danger of reaction is avoided, for there is no sudden change of temperature; and moreover the sheet of oil protects the surface from atmospheric influences.

3. It acts as a fuel-food, not only preventing waste of tissue, but actually increasing the bulk of the little patient.

4. It does not depress, but on the contrary appears to exhilarate.

As regards the progress of the aliptic art, the literature is being added to every day. From time to time have appeared articles in our medical journals, one even in the *Popular Science Monthly*, of October, 1882. Perhaps Dr. S. Weir Mitchell has done more than any other in this country toward the revival of this art, and his marvellous cures in chronic cases of debility, nervous prostration, anæmia, emaciation, amenorrhœa, and even phthisis, as described in his little book on *Fat and Blood*, and sundry articles in journals, bear evidence to the efficacy of this treatment by massage, as he chooses to call it. It is significant that he requires the use of cocoa oil or vaseline in conjunction with friction, and hence we have, after a score of centuries, the art practised by the Roman aliptæ brought forcibly before us again, but the aliptæ are now dubbed *masseur* and *masseuse*, while the aliptic art comes to us in French disguise as *massage*.

The rubbing of the body with oil requires system. It cannot be properly carried out by a novice. It is more than mere friction of the skin. The aliptic art should be taught in nurses' training schools by competent lecturers and demonstrators. The accomplished aliptæ of to day must have some knowledge of anatomy, of physiology, have strong, soft hands, and a great deal of patience.

I cannot here go into details with regard to the method of rubbing. Suffice it to say, that beside friction of the skin, firm pressure is necessary, blows with the soft parts of the hand, and a kneading of the whole substratum of muscular tissue. The rubbing should be in the direction of the current of venous blood, and all the muscles of the body should be treated in groups, one after the other. The laws of Hippocrates with regard to friction are still applicable: "Violent friction hardens the tissues; gentle softens; long-continued diminishes; moderate increases."

Dr. Mitchell has shown that the temperature rises in patients thus treated, probably due to the active increase of the nutritive processes in the tissues which rubbing undoubtedly causes. The circulation is visibly increased in all parts so treated. The manipulations become exhilarating and soothing to the patient. The venous circulation being assisted by rubbing toward the heart, it is probable that the excretion of disintegrated matter and the entrance of arterial blood into the tissues are hastened. As to oils to be used, we have some that are simple, emollient, nutritious, non-irritant, and protective from changes in temperature, such as olive, cocoa, flaxseed, and sesame, then lard and suet, and the sweet principle of oils, glycerine, any of which can be made fragrant and grateful to the patient by the addition of a few drops of oil of roses, violets, lavender, or rosemary. We have a large number of oils which are stimulant and rubefacient, notably cajuput, anise, cinnamon, cloves, caraway, fennel, pepper, nutmeg, peppermint, and rue. Oil of sage is astringent, turpentine styptic, bitter almond oil sedative, croton and mustard irritant. Almost any quality of oil—astringent, rubefacient, anæsthetic, irritant, antiseptic—may be obtained by combination with different drugs.

For paralysis and many other nervous disorders, for all diseases accompanied by general venous stasis, for all the chronic inflammations, for insomnia, atrophy of the muscles, obesity, syncope, for superficial pains, for establishing collateral circulation after ligature of arteries, for obtaining healthy action of the skin, for exercise and nutrition of the body, and I may add for treatment of all specific infectious fevers—until we shall discover some medicine certainly destructive to specific bacteria—for all these the aliptic art is our chief scientific remedy.

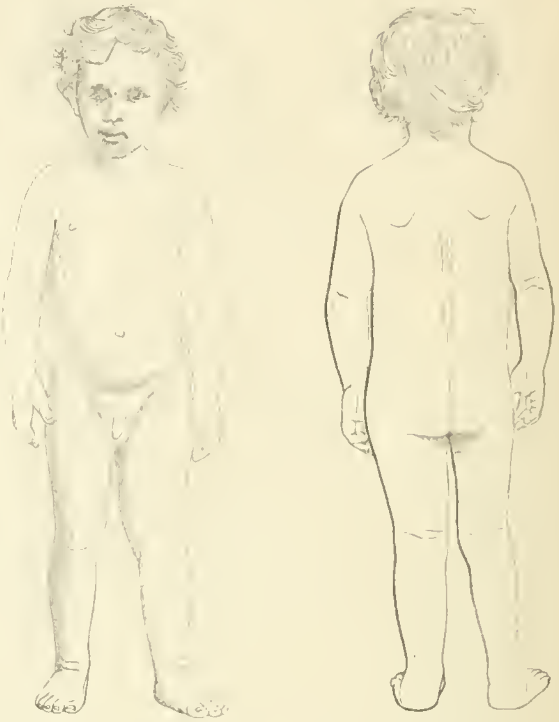
CONGENITAL UNILATERAL ATROPHY.

BY SUMNER PIXLEY M.D.,
OF PENINSULA, SUMMIT COUNTY, OHIO.

ON the twenty-second day of August, 1876, I was called to see Mrs. A. M., who was in the labor of her third confinement. (Her first child was a boy, who lived eleven days, and died of some disease of the lungs, as reported to me. Her second child, a girl, now nine years old, is well formed, and has always enjoyed good health.) There was nothing unusual in her labor. It was perfectly natural, the child, a boy, crying lustily as soon as born. I discovered at once *that the entire right side of the child was much smaller than the left*, a fact which caused much curiosity and speculation among the lady attendants present. From his birth to the present time the boy has been so healthy as to require no medical aid, but continues to grow with the same deformity that he had at birth. The exact measurements of the boy, taken at two different times, are as follows:

	Age, 4 years 6 mos. Height, 39½ inches.		Age, 6 years 6 mos. Height, 45 inches.	
	Right Side.	Left Side.	Right Side.	Left Side.
	Inches	Inches	Inches	Inches.
From sternum to spine, around point of shoulder,	$11\frac{5}{16}$	$12\frac{6}{16}$	$11\frac{8}{16}$	$13\frac{8}{16}$
Length of humerus,	$7\frac{6}{16}$	$8\frac{6}{16}$	9	$9\frac{12}{16}$
Length of whole arm,	$15\frac{3}{16}$	$16\frac{15}{16}$	$15\frac{12}{16}$	$17\frac{6}{16}$
Circumference of shoulder,	$7\frac{2}{16}$	$8\frac{10}{16}$	8	$9\frac{2}{16}$
Circumference of forearm,	$6\frac{11}{16}$	$7\frac{1}{16}$	$7\frac{10}{16}$	$8\frac{10}{16}$
Length of whole leg,	$18\frac{12}{16}$	$19\frac{3}{16}$	22	$23\frac{4}{16}$
Length of femur,	$10\frac{5}{16}$	$10\frac{9}{16}$	12	$12\frac{9}{16}$
Length of tibia,	$8\frac{8}{16}$	$8\frac{8}{16}$	9	$9\frac{8}{16}$
Circumference of femur,	$12\frac{2}{16}$	$14\frac{6}{16}$	14	16
Circumference of knee,	$10\frac{2}{16}$	$11\frac{1}{16}$	$11\frac{4}{16}$	$12\frac{3}{16}$
Circumference of chest, over nipple,	$10\frac{2}{16}$	12	11	$12\frac{4}{16}$
Circumference of abdomen, over umbilicus,	$11\frac{4}{16}$	$12\frac{6}{16}$	$12\frac{6}{16}$	$13\frac{2}{16}$

The right side of the head is much smaller than the left, and the superior and inferior maxillary bones of the right side are so diminished in size that the teeth do not touch within one-sixteenth of an inch, consequently all fine mastication is performed on the left side of the mouth. The first incisor of *left* superior maxillary made its appearance at eleven months, and in the inferior maxillary soon afterward. The remainder of his teeth on this side came in regular order to the full number. The first incisor of *right* superior maxillary made its appearance at seventeen months, and the first of the inferior maxillary at twenty months, the rest following in regular order, with the exception of the last molar, which has not yet appeared. Motion, temperature, and sensation in both sides are alike, and his intellect is equal to children of his age. He is right-handed, his tongue, when protruded, points to the right, and in erection his penis points towards the right side. There has been no hereditary taint in his ancestors as far back as I can trace. The appearance of the boy is well shown in the illustrations from photographs taken at the time the first measurements were made.



ACUTE TONSILLITIS,

AS OBSERVED AND TREATED IN THE DEPARTMENT FOR DISEASES OF THE THROAT AND NOSE OF THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE.—EFFICACY OF THE COMPOUND GUAIAC GARGLE AND OF THE SALICYLATE OF SODIUM.

BY S. SOLIS-COHEN, A.M., M.D.,
ONE OF THE CLINICAL ASSISTANTS; DEMONSTRATOR OF PATHOLOGY AND MICROSCOPY.

FOR therapeutic purposes, according to the teaching of Prof. J. Solis-Cohen, and as practised in his clinics, cases of acute tonsillitis may be divided into two classes: 1st, simple inflammatory or local; 2d, rheumatic or constitutional.

Each of these classes might be extensively subdivided, according to the most prominent objective or subjective, anatomical or pathological manifestations. Such refinement in nomenclature (for this alone is it, practically) is, however, unnecessary in arriving at the therapeutic indications. For whether the tonsillitis be unilateral or bilateral, or the two glands be affected consecutively—whether the inflammation be superficial or deep-seated, circumscribed or diffuse, limited to the follicles, or involving all the component structures—whether the morbid process be confined to the tonsil, or extend more or less widely among neighboring tissues—any particular case having been properly assigned to one of the two groups mentioned, its treatment need not be materially changed.

Of course, should suppuration threaten or occur, or should the enlargement of the tonsils be such that respiration becomes seriously impeded, incision, scarification, or other appropriate surgical procedure may be required. But when the patient is seen early, say within the first twenty-four hours, such accidents are very unlikely; if, indeed, the tendency to grave manifestations be not entirely averted. At all events, they did not arise in any of the cases treated at the Polyclinic.

The treatment has been as simple as it has been eminently successful; the principal reliance having been placed upon two remedial measures only, each of which seems entitled to be termed specifically appropriate for the particular group of cases in which it has been employed.

I. Simple Inflammatory Tonsillitis.—When the principal objective symptoms consist in alteration of voice, and more or less redness and enlargement of one tonsil, with or without swelling of the glands at the angle of the jaw; there being little constitutional disturbance; the pain complained of being chiefly due to tension; the odynphagia which is usually present having manifested itself after the swelling of the gland has been noticed; the disease may be considered as a local affection.

The treatment adopted in such instances is a modification of the old and well-tried *guaiac* treatment; and consists in the employment as a gargle of a mixture long known throughout the West and Southwest under the name of "diphtheria mixture" and similar titles. This is known in the House Pharmacopœia as the *Gargarysma Guaiaci Composita.* Two fluidrachms each, of the ammoniated tincture of guaiac and the compound tincture of cinchona, are mixed with six fluidrachms of clarified honey, and shaken together until the sides of the containing vessel are well greased. A solution, consisting of eighty grains of chlorate of potassium, in sufficient water to make four fluidounces, is then gradually added, the shaking being continued. If the apothecary is careful to make this preparation *secundum artem,* a not unpleasant mixture will be obtained. Without due care, however, the resin will be precipitated.

The patient is directed to gargle with this mixture freely and frequently, at intervals varying from every half-hour to every three hours. In some instances, a saline cathartic is first administered. Should any of the guaiac mixture be swallowed, it is considered rather beneficial than otherwise, and its deglutition is sometimes recommended.

Relief is usually experienced within a few hours, and recovery is prompt. Patients often return only to report their cure.

A young colored man had been attacked about eight hours before presenting himself at the clinic. When the writer saw him, there was great enlargement of the left tonsil, causing intense pain, and preventing deglutition of solids. The submaxillary gland and some of the cervical glands of the same side were so much swollen that he was compelled to bend his head down toward the right shoulder. This patient reported himself well, sixteen hours after coming under treatment. In his case, one ounce of Rochelle salts was first administered, and the compound guaiac gargle was directed to be used every two hours; but the relief following the first application was so grateful, that, in order to secure freedom from pain, the patient resorted to his medicine every half-hour or so.

A little girl of seven years was brought to the clinic with unilateral folliculous tonsillitis, a few hours after she had begun to complain of pain in her throat, and was told to use the compound guaiac gargle at intervals of two hours. She did not return until a month later—June 16—when she was brought for treatment of an acute coryza. Her mother remarked: "That medicine for her throat worked like a charm. She got worse for a few hours, but was well next morning."

Several similar cases of prompt relief could be cited in addition.

II. Rheumatic or Constitutional Tonsillitis.—When the first manifestation of the disease (excluding prodromata of headache, malaise, etc., which may or may not be present) is intense pain upon deglutition, causing great accumulation of saliva from unwillingness to swallow the excessive secretion; examination of the fauces revealing perhaps a slight congestion—perhaps nothing; more or less febrile reaction soon ensuing: the case may be assigned to the second or rheumatic group.

In these cases, the odynphagia cannot be explained by anything visible upon inspection. It is sometimes referred to a point representing the entrance into the œsophagus, and examination with the laryngoscopic mirror will show some redness of the mucous membrane covering the arytenoid and supra-arytenoid cartilages and the pharyngeal surface of the cricoid cartilage. More or less soreness in the throat is constantly present; respiration often becoming painful, and phonation excessively so.

Some hours after, as the headache, pulse, and temperature decline, one or both tonsils become enlarged; usually one consecutively to the other. The follicles are often distended with a caseous or sebaceous material, which, under the microscope, is seen to consist of scattered (pavement) epithelial cells, some oil globules, and a mass of granular detritus, mingled with which are the spores and filaments of the *Leptothrix buccalis, Oidium albicans.*[1] rod-bacilli. and other fungi, as usually found in the secretions both of healthy and of diseased tonsils.

---

[1] Or something which I cannot distinguish from it. I have seen this fungus in but one case, and curiously enough, in this instance there were no aphthæ upon the mucous membrane covering the hard palate; though I have observed aphthous sores in several of these cases, and especially in the neighborhood of the incisor teeth.

Some drops of blood from an inflamed tonsil, in one of these cases, showed great deformity of the red corpuscles, and unusual size and number of the white corpuscles, which were more than ordinarily granular; but no micrococci could be detected therein A drop of blood from a finger of the same patient presented nothing abnormal.

Usually, as the pain in the throat subsides, muscular soreness occurs in the neck, back, and loins; oftentimes in the sterno-cleido-mastoideus of the side corresponding with the tonsil first enlarging. Sometimes the soreness is experienced in one or more of the limbs; and some one of the larger joints may become more or less stiff, though neither red, swollen, nor painful. Indeed, rheumatic or rheumatoid pains may flit from one portion of the body to another, during several days. In rare instances, transient albuminuria follows.[1]

These cases are treated with *salicylic acid* or *salicylate of sodium*. The constipation usually present, due either to the disease or to the remedy, is relieved with an appropriate saline cathartic.

The following formula makes a pleasant and efficient mixture:

℞.—Sodii salicylatis, ... ʒij.
Ol. gaultheriæ, ... ♏j (vel. q. s.).
Liquoris ammonii citratis,
Syrupi simplicis, ... āā f℥ij.—M.
S.—A tablespoonful every two hours.

As soon as the pains are relieved, the intervals are lengthened; or salicylate of quinine or of cinchonidine is substituted, as a tonic, in five-grain doses at intervals of four or six hours. Ringing in the ears (an occasional occurrence) calls for cessation of the salicylates; when it usually passes away. In one case, where persistent, it was relieved by small doses of the infusion of digitalis. During the progress of the more acute symptoms, the patient's comfort may be promoted by allowing small lumps of ice to melt in the mouth from time to time, or even by the use of the compound guaiac gargle.

Stiff-neck, the most annoying of the muscular complications, should it be severe, is relieved by faradization more promptly than by medication; the negative electrode being applied to the painful spot, or moved along the course of the sterno-cleido-mastoid muscle, the positive electrode being grasped in the hand of the same side. The same measure is, of course, applicable to other muscles.

HOSPITAL NOTES.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

Service of Louis A. Duhring, M.D.,

PROFESSOR OF DISEASES OF THE SKIN IN THE UNIVERSITY OF PENNSYLVANIA.

(Reported by Henry Wile, M.D.)

SCORBUTUS WITH FOLLICULAR PURPURA.

The patient before us, a Hungarian by birth, and speaking only his native language, can give us no information in regard to his condition. His history must remain blank. On examination, it is found that the lesions are, for the most part, confined to the lower extremities, and appear in the form of minute, pin-head-sized, dark-red, some confluent, but, for the most part, discrete spots, occupying the tissue around the hair-follicle. Passing the hand over the skin, we find it harsh and dry. Pressing on the spots with the finger, they do not disappear. They are plainly due to hemorrhages, and to no inflammatory process. These hemorrhages have taken place around the hair-follicles, and are by no means recent, as is indicated by that dark color.

The general surface of the body has a dark-yellow hue, and examining the general condition of the patient we find absence of fever, tongue normal, but the gums soft, spongy, and showing a tendency to bleed. With these observations, together with the lesions on the skin, we have no hesitation about the diagnosis. The dermal manifestations of this disease are of variable size. Here the lesions are small, often they are in the form of large patches. The disease is the result of malnutrition, want of fresh vegetables, fresh meat, etc. The treatment will consist mainly of a suitable nutritious diet. No local applications whatever are indicated.

CHRONIC TINEA TONSURANS IN A NUMBER OF BOYS.

Eight little boys, with ages ranging between seven and ten years, are sent here for advice on account of a certain chronic affection of the scalp. Coming from a large institution, and presenting lesions similarly located, and with similar appearances, naturally leads us to suspect a contagious disease, especially a disease caused by the presence of a fungus. The diseases occurring thus are two in number, *Tinea tonsurans* caused by the tricophyton fungus, and *Tinea favosa* caused by the *Achorion Schönleinii*. The latter is rare, but the former is quite common, occurring often endemically in large institutions for children.

When a number of such cases as these are brought before us for examination, the matter of the differential diagnosis is most important. For certain forms of eczema, seborrhœa, psoriasis, may simulate this disease so closely that nothing but the microscope will give the decision.

Where this disease once gets a hold in a large school or institution it becomes a difficult matter to cure it, and sometimes it defies every method of treatment. In regard to the prognosis, we must make a distinction between acute and chronic ringworm, always remembering that the acute form yields, as a rule, readily to treatment, while the chronic form may be exceedingly obstinate.

The first of these boys, about eight years old, presents, on the top of his head, a chronically inflamed spot about the size of a silver half-dollar, and over the vertex are small, pale, scaly spots. On none of the lesions is the hair absent, and seizing a hair with the forceps, we see it is not loose, and in extracting it considerable force must be used. The question is, have we here a case of seborrhœa, eczema, or ring-worm. We may exclude seborrhœa, on account of the infiltration and inflammation. The points in favor of eczema are the facts that there are no bald patches or loose hairs; yet the fungus sometimes attacks the epidermis, and not immediately the hair-follicle. In this case, the microscope alone can give satisfaction, but the disease is probably parasitic.

The second boy states that he has had the affection on the scalp for five years. The lesions have the same general characteristics as those in the first case. Having existed for such a long time, we should expect to find those short, broken-off hairs which are of special diagnostic value; but on examination we can find none. Where this disease is so chronic, and has been under different modes of treatment, it may become difficult to see those features which are characteristic. In this case, we also find on the back of the right wrist an irregularly shaped, ill-defined patch, about the size of a silver dollar. It is of five weeks' duration, irregularly round in shape, somewhat elevated, pale-red, and spotted with a scant amount of fine dry scales. It also has been modified by treatment, but it is *Tinea circinata*.

---

[1] This has not been met with at the Polyclinic, but in private practice.

The third case is almost identical with the one just looked at; we find a similar scaly patch on the scalp, but without those broken-off hairs. Having been under treatment, we should judge that the cases thus far are on the road to recovery.

In the fourth case we have another picture, one which is eminently characteristic of *Tinea tonsurans*, where we find any number of those broken-off hairs. Here we undoubtedly have a clear case of chronic ringworm. This case presents on the scrotum and about the groins a papular and vesico-papular eruption, which has no connection with the other disease, but is distinctly eczematous in character.

The fifth case is much like the first. There are no broken hairs, but those present are matted down to the surface of the scalp, not with exudation, but with layers of dry, yellowish-white scales.

The sixth case presents a diffused patch similar to the others, but here and there the characteristically diseased hairs can be seen.

The last two cases present lesions, which in location and general appearance are like the foregoing.

Thus it is seen that only two boys show the disease typically, so that in these cases there can be no doubt as to the diagnosis. In the other cases the microscope will have to be resorted to before a positive diagnosis is given, but we may say that there is little doubt that all the cases are instances of the same disease. It is eminently a disease of childhood, adults never being affected. The skin of the adult seems to be no habitat for the fungus, so that when the patient becomes an adult the disease disappears. As this takes time, and as there is danger of infection, active treatment should always be resorted to.

As regards treatment of these boys, representing instances of chronic ringworm of the scalp, nothing short of a thorough, severe, and prolonged application, together with long-continued depilation can bring about a cure. Depilation is extremely important, it must be carried on systematically. As regards the value of parasiticides, a number of remedies are found useful, *e. g.*, sulphur ointment, ointment of the nitrate of mercury, ointment of the oleate of mercury, iodine, carbolic acid, and these remedies in various combinations. When the disease is circumscribed, applications of croton oil offer perhaps the best means of treatment, applied with a view of bringing about artificial kerion. The treatment is severe, but by no means so painful as one might suppose. Applications may be made every day or every other day, according to the sensibility of the scalp, a simple poultice being applied in the mean time. As soon as kerion sets in the hairs become loose, and are very easily extracted, after which cure sets in rapidly. Where the disease is diffuse, occupying the greater part of the scalp, a part only should be treated by croton oil; other parts may be treated with some parasiticide in the form of an ointment, *e. g.*, chrysophanic acid two drachms to the ounce. Where it is not advisable to use the oil, one of the ointments named above, or chrysophanic ointment may be applied together with depilation. The scalp in chronic ringworm stands strong remedies remarkably well, and there is little danger of getting the remedies too strong. Equal parts of ointment of the nitrate of mercury and sulphur, or equal parts of the oleate of mercury (seven per cent. strength) and sulphur ointment may be mentioned as useful.

As regards prognosis in cases of one or two years' standing, when lesions are diffuse, as in several of these boys, from six months to one year will probably be necessary to bring about a cure; other cases require a longer time, even two years will be necessary to bring about a successful result. This remark applies to bad, neglected cases in public institutions, where the scalp is dotted with broken-off hairs on a level with the skin. In these virulent cases, the disease often crops out in the face of active treatment, and this continues its course, being better and worse from month to month.

MEDICAL PROGRESS.

Bismuth Dressing.—The bismuth dressing recommended by Kocher has given excellent results in the hands of M. Riedel, of Aix-la-Chapelle, both in fresh and septic wounds. Its employment is in the highest degree appropriate for drying up the secretion on the surface of wounds and hastening the closure of their borders. This last effect is equally manifest when bismuth is applied to a wound of the pleura or peritoneum, as M. Riedel has observed from experiments on animals; this being due to a constant disengagement of very small quantities of nitric acid, which is endowed with a plastic action. This effect may be surpassed when very large quantities of the bismuth are applied, and eschars may result, though this has not occurred in sixty-one cases of various injuries, eight of which were complicated with erysipelas. On account of the occasional erysipelatous complication, M. Riedel has combined corrosive sublimate with the bismuth dressing. In twenty-three cases dressed with the combination there was no phlegmon, and only one case of erysipelas.—*Gaz. Méd. de Paris*, May 12, 1883.

Treatment of Zymotic Pyrexia by Inhalation of Ammoniated Chloroform.—So long ago as 1853, Dr. B. Ward Richardson treated a case of what was then called phagedænic croup by inhalations of the vapor of chloroform and ammonia in combination. In the epidemic which occurred at Mortlake at that time, he had found, on post-mortem examination of three fatal cases, separation of fibrine in the heart, and had assigned the cause of death to the resultant obstruction. He was led, thereupon, to administer ammonia very freely, by the mouth, in such cases, in order to maintain the fluidity of the blood. In the particular case to which he refers, the patient was a child, six years of age, who absolutely refused to swallow medicinal doses of ammonia. In the house in which he lived there had been a death of another child from the disease, and as, in this new case, death seemed certain, he determined to administer the ammonia by inhalation in combination with chloroform, the parents of the child yielding a willing assent to what they felt was, in fact, a last chance. With very little trouble, he produced a gentle narcotism with the combined vapors, and was then able to increase the quantity of ammonia considerably. He kept up the inhalation for fourteen hours, administering food by enemata. The patient began to breathe with comparative ease within an hour after the commencement of the inhalation. In the course of three hours, he had a loose cough, with expectoration, which was easily ejected, although there was continued sleep. The fever rapidly subsided, and, when the vapors were finally withdrawn, there was quick return of consciousness, with complete subsidence of the acute symptoms. The recovery was rapid and complete.

In connection with this subject, he was once led to inquire what effect the vapors of ammonia and chloroform alone and combined had on putrefactive changes. He learned thereupon that each vapor in its separate state is a remarkable antiseptic, and that the two act admirably in combination.

Experiments have yielded a demonstration of a specimen of blood which had been perfectly preserved in the fluid state, and free from any trace of decomposition during twenty years.

Recently he has recurred to his original plan of administering the vapors of chloroform and ammonia in combination in cases of zymotic fever, and thus far the practice seems exceedingly easy, and to promise valuable results.

He takes an alcoholic solution of ammonia (.838 alcohol saturated with ammonia), and mixes it in equal parts with chloroform or methylene bichloride. When the solutions are mixed, any separation of water that may occur is removed, and in this way a clear mixture of ammoniated chloroform is obtained ready for use. In administering this compound by inhalation of the vapor, two fluidrachms of it are put into a small Wolf's bottle, and the bottle connected with a leather inhaler armed with an expiratory valve. The mouth-piece of the inhaler is held close to the mouth, and the patient is instructed to inspire until bubbles of air are drawn pretty freely through the fluid in the bottle. The inhaler is in this manner charged with the vapors which are drawn into the lungs.

From the first, the ammonia vapor is deprived of much of its pungency by the presence of the chloroform, and in time, as the narcotic begins to take effect, the pungency of the ammonia is covered so effectually that larger quantities of it can be inspired without cough or irritation. During the past week, in a puerperal case, under the care of Dr. Rogers, in which he suggested this method in consultation, the patient inhaled freely every two hours for three days without the slightest discomfort, and with obvious direct advantage. The effects of the inhalation seem to him to extend in four directions: 1. Under the sedative action of the narcotic, relief from pain is obtained, and repose, if not actual sleep, is secured. 2. Under the combined influence of the vapors, there is reduction of temperature. 3. Under the influence of the ammonia, there is a sustained fluidity of the blood and a production of freedom of secretion. 4. Under the action of the combined vapors, there is an antiseptic result which is always favorable.

The principle is that through inhalation we should learn how to reduce zymotic fever at once, with direct precision, and without employing any of those medicinal agents which have to pass slowly into the system by absorption through the stomach, have to pass out of the system by slow elimination, and after all do not immediately command the position that ought immediately to be attained in the management of acute disease.

There are several vapors which reduce temperature more rapidly than those named, and it is probable that there are vapors less complex, and yet possessing the same properties. It is also probable that in some forms of zymotic fever, more or less alkaline vapor may be required than in other forms.—*Lancet*, June 9, 1883.

Wound of the Thoracic Duct.—M. Bœgehold, when assistant to Wilms, saw, during the extirpation of a tumor of the neck, a milky liquid flow from the wound, which proved to be chyle, and without doubt came from the thoracic duct. The wound was tamponed and the flow arrested. The patient recovered, but subsequently had a return of the tumor in the same place, which, on examination, proved to be carcinomatous. Bœgehold has not been able to find a similar example in medical literature.—*Gaz. Méd. de Paris*, May 12, 1883.

New Reaction of Urine and Milk.—M. Ch. Richet has discovered that iodohydrargyrate of potash, by the reduction of metallic mercury under the influence of organic substances, enables us to easily measure the extractive matters contained in the urine. This salt, which is decomposed by neither urea nor uric acid, is almost instantly attacked by the extractive matters, and is precipitated as metallic mercury. From a series of experiments, M. Richet has established the fact that there is a very close relationship between the quantity of urea and the amount of extractives in the urine. This reaction is not confined to the extractive matters of urine, but is applicable to other physiological secretions, as milk. It is known that milk contains a substance, the nature of which is but little known and possessing the reaction of ptomaines, which instantly throw down cyanide of iron from ferrocyanide of potash, and then, by the addition of a drop of neutral chloride of iron, give rise to the formation of Prussian blue.—*L'Abeille Méd.*, June 4, 1883.

Hydatid Cysts of the Spleen.—During the past twenty years, forty-seven cases of hydatid cyst of the spleen have been observed in five thousand patients in l'Hôtel Dieu de Rouen. Among these, the heart, muscular tissue, epiploon, broad ligaments, brain, and lungs, have been affected in twenty-three cases. The remaining twenty-four had had hydatid cysts of the liver, and in only one of these did the autopsy show simultaneous affection of the liver and spleen by the hydatids. Though there is no question as to the occurrence of primary cysts in the spleen, they are not frequent.

The diagnosis of splenic cysts is difficult. They simulate, in their onset and progress, functional troubles of other organs. A patient, whose history is reported by M. Gerin-Rose, gradually lost flesh for two years; he had epigastric pains for a year, digestive troubles, vomiting of black material, liquid stools, and inability to retain food, and presented the physical signs of cancer of the stomach, although the volume of the tumor was against this diagnosis; an exploratory puncture revealed its true nature, which was further substantiated by a post-mortem examination—an hydatid cyst of the spleen. In a case reported by Legroux, the patient had received a blow in the side three weeks before the appearance of the tumor. The rapid growth of the tumor led to a diagnosis of abscess of the abdominal wall by M. Robert, but Legroux detected the hydatid thrill, and his diagnosis was confirmed by the autopsy. When the splenic tumor exists simultaneously with a cyst of the liver, as in the case of a patient of M. Leudet, the latter is easily recognized during life, but the former will be obscured until the autopsy. As regards treatment, M. Sevestre punctures recent cysts with retractile walls, but in old tumors, Récamier's proceeding, incision with a bistoury and the thermocautery with strict antiseptic precautions, is preferable.—*L'Union Méd.*, June 23, 1883.

Extirpation of the Kidney.—Dr. Israel performed this operation on a young woman on May 6th. Simon's incision was used, commencing at the middle of the twelfth rib and running down for two and three-fifths inches. The disease was found to be pyonephrosis, as was diagnosticated. The patient died on the fourteenth day.—*Deutsch. med. Wochenschr.*, June 13, 1883.

Resorcine.—Braum has used resorcine in three hundred cases of ephemeral fever of infants, in which there was hyperpyrexia, and invariably it produced a fall of temperature to normal, and in a few cases also great lowering of the temperature with profuse perspiration. The usual dose was grs. xlv, repeated during the day, with no attendant nervous phenomena. In paludal fever resorcine is but very little, if at all, inferior to quinine. Ugo Bassi has reported 17 cases of recovery of 20 cases in which it was used. The dose varies from grs. xxx–xlv during twenty-four hours, to be given for several days. Its cheapness is an especial recommendation. Skibnewsky has reported two rapid recoveries from erysipelas after the hypodermatic injection of a one-twentieth solution. Between ten and twenty injections were made in the erysipelatous parts. These injections were followed in less than ten hours, not only by disappearance of the fever, but by an abnormal fall of temperature. It has been successfully used in parasitic skin diseases. Justus Andeer has recently reported a case of malignant pustule, with erysipelatous areola which had invaded a large part of an upper limb and was beginning to show signs of general infection. The case was cured in a few days by the application of a thick coating of resorcine and vaselin 50–100 to the affected limb, which was then enveloped by gauze and a bandage. On the following day the pain and tension had diminished, the surface of the limb was taking on a healthy aspect and the erysipelato-vesicular eruption disappeared. Resorcine produces no local irritation, does not produce hemoglobinuria as does naphthol, nor symptoms of poisoning, as do carbolic and pyrogallic acid, etc.—*L'Union Méd.*, July 19, 1883.

Hygienic and Therapeutic Properties of Cresses.—According to an analysis by M. Chatin, cress contains an essential oil of which the base is allyl, a bitter extract, iodine, iron, phosphorus, and certain salts. M. N. Gueneau de Mussy reports the case of a woman of sixty years who had been unsuccessfully treated for fifteen years for chronic eczema. The eczematous eruption had attacked the tongue and rendered deglutition painful and difficult. After ordering arsenic and other remedies without result, M. de Mussy prescribed a large quantity of water cresses every day. In five months there was very decided amelioration of the symptoms, and the eruption had entirely disappeared from the tongue. This prescription was equally efficient in another chronic case.—*Gaz. Hebdom*, June 22, 1883.

Case of Violent Hemorrhage from the Left External Auditory Meatus Following a Cold Abscess; Subsequent Rupture of the Left Internal Carotid, Causing Death in a Few Seconds.—Dr. R. B. Davy, of Cincinnati, reports the case of a little girl, three years of age, suffering from restlessness, coated tongue, sore throat, and slight fulness of the left side of the neck. In the act of examining the throat (the child resisting), an abscess of the left ear broke and discharged about a teaspoonful of reddish pus. After a few hours a violent hemorrhage from the ear set in, and in the course of two days fully a quart of blood had been lost. Most of this quantity was discharged at two bleedings, the pillows being stained only with small spots in the intervals. The hemorrhage ceased spontaneously, and for nearly a week the ear discharged pus, gradually losing the reddish cast. The auditory canal was now examined with reflected artificial light, and the membrana tympani found to be intact. The child was improving, though very pale. On the fifth day after the last hemorrhage, another quite as violent as the first occurred. The ear was now plugged with a bit of sponge, and the bleeding was checked. Simultaneous with the plugging, there appeared a swelling about the size of the longitudinal half of a hen's egg extending from the left mastoid process downwards and forwards. This swelling increased in size until late in the afternoon when the plug was forced out of the ear, the blood spurting at least a foot from the child's head, and the tumor diminishing in size. The ear was now more firmly plugged and ice-bags applied to the swelling, which had returned immediately. The next day the swelling was perceptibly smaller, and had a leathery feel on firm pressure; but the third day afterwards it again increased in size and showed signs of suppuration, though there was no pointing externally. On the following afternoon, the left internal carotid artery ruptured in the mouth, and the child bled to death in a few seconds. The post-mortem examination revealed at the site of the swelling a deep-seated abscess, whose contents had come in contact with and injured the coats of the vessel in question, causing them to give way. The loss of blood during the fatal hemorrhage amounted to but little over half a pint. Careful inquiry for a history of hemorrhagic diathesis was made, but no facts pointing to such a condition could be elicited. The Doctor concludes that the first hemorrhage was caused by ulceration of the coats of the posterior auricular artery.—*Cincinnati Lancet and Clinic*, July 21, 1883.

Trephining for Traumatic Rupture of the Middle Meningeal Artery.—Krönlein reports two cases. The first case, seen on the day after the injury, was in a profound stupor; no paralysis; pulse 58. Subsequently there was incomplete paralysis of the right leg, complete paralysis of the right arm, ptosis, and facial paralysis. Hemorrhagic effusion from rupture of the middle meningeal artery was diagnosticated, and Krönlein performed trepanning on the fourth day, but no extravasation was found. Post mortem examination showed a large hemorrhagic effusion, which had escaped from a branch of the middle meningeal, pressing upon the anterior central convolution.

The second case, male, æt. 60, had a fall, became unconscious, and passed into a comatose condition. The left side was paralyzed, there was slight facial paralysis, with relaxed sphincters, and retarded pulse. There was also conjunctival ecchymosis of the right side, doughy infiltration of the skin and soft parts of the temporal region, and pressure in that region seemed to be painful. Krönlein diagnosticated fracture, with rupture of the middle meningeal artery. The patient was trephined, and an extravasation found, there being also a depressed fracture pressing on the brain. A very large amount of coagula was removed. Two months after the operation, the patient was well, with the exception of slight paralysis of the face (mouth).—*Centralbl. für Chirurgie*, No. 28, 1883.

Puerperal Eclampsia.—Eclampsia, says Donati, should not always be considered as the clinical expression of identical pathogenic states. He gives three forms of puerperal eclampsia. 1. *Eclampsia from mechanical causes*, by compression of the aorta by the gravid uterus, giving rise to cerebral hyperæmia and œdema, with or without albuminuria. In primiparæ this form is caused by the resistance of the abdominal walls, and in multiparæ by tight clothes and hydramnios. 2. *Reflex eclampsia*, from vaso-motor troubles of the cerebral vessels under the influence of excitations coming from the nerves of the uterus. 3. *Toxic or dyscrasic eclampsia*, in anæmic, septicæmic, or other alterations of the blood. These forms are not always easily recognized in practice; yet each has its therapeutical indications. In the first, drastics, derivatives, and blood letting are indicated. In reflex eclampsia, chloroform, ether, opium, and chloral are indicated; and in the toxic form, purgatives or diuretics, according to the nature of the case.—*Gaz. Hebdom.*, July 20, 1883.

Alimentation of Young Children.—The following are the conclusions presented by the Committee to the Eleventh German Physicians' Association:

1. The natural food of children—mother's milk, is to be preferred above all others.
2. Only in case of positive contraindication, or non-appearance of the milk, should a wet-nurse be employed.
3. Only in case of impossibility of obtaining a wet-nurse should artificial food be employed.
4. The contraindication against the mother nursing is actual disease or a predisposition to disease.
5. Hereditary syphilis demands the milk of the mother; that of a wet-nurse should only be used with great caution.
6. Examination of a given specimen of milk furnishes no clue as to its value in a given case.
7. Good cow's milk alone is fit to take the place of woman's milk as food for the child.
8. The quality of good, sweet cow's milk, for a child which must be artificially fed, is one of the most important essentials in the hygiene of young children.
9. All childrens' foods, including Liebig's soup (food), on account of the large quantity of starch contained in them, are unfit for children during the first month.—*Berlin klin. Wochenschr.*, July 18, 1883.

Clinical Characteristics of Wool-sorters' Disease.—The following memorandum has recently been prepared for use in the inquiry now being conducted by Mr. Spear into the occurrence of anthrax amongst men employed in hide warehouses, tanneries, etc.:

The "Internal form" or Anthrax fever.—Premonitory symptoms (of variable duration): Chilliness, aching or stiffness of limbs, and mental depression; restlessness, sense of constriction of chest, and oppression of breathing; headache, dizziness, nausea, or, less frequently, vomiting. Stage of full development. Notwithstanding the indefinite premonitory symptoms, the stage of full development is generally somewhat sudden and unexpected in its onset, so as to cause much alarm. The prostration and restlessness become extreme; there are præcordial anxiety and dyspnœa; blueness of the face and extremities (cyanosis) is conspicuous; and the patient may die within twenty-four or thirty-six hours with all the appearances of collapse or of asphyxia. A fatal termination is, however, more often postponed until from two to five days after the commencement of this stage. Other nervous phenomena—muscular paralyses, convulsions, or tetanic spasms—are then likely to develop themselves; and evidences of various acute local congestions (especially of the lungs, less frequently of the gastro-intestinal tract) are rarely wanting. Delirium is often absent; and the temperature is irregular. Exacerbations, alternating with more or less complete remissions, of the more urgent symptoms constitute usually a striking feature of the disease. Recovery is not so rare as has been supposed, even in fully developed attacks; but death may occur from a relapse, or from secondary septic processes. The body after death usually undergoes rapid decomposition, with blue discoloration and swelling, especially about the neck.

[Before the disease was identified amongst the wool-sorters, deaths were usually referred to one of the more prominent local symptoms of anthrax, and were registered as from "pneumonia," "enteritis," "peritonitis," "meningitis."]

The "External Form" of the Infection, or Malignant Pustule.—The malignant pustule attacks almost always parts of the body habitually uncovered, and most frequently the face It commences as a small papule, which quickly develops into a vesicle, and this, being broken, pours out a little watery exudation. The base of the vesicle, and the surface immediately adjacent, dies; so that in about three days after its appearance the lesion consists of a small central black eschar, with a raised border of inflamed and tumid skin upon which vesicles are likely to be developed; a crop of secondary vesicles surrounding thus the central eschar like a wreath. The neighboring lymphatics and glands are speedily implicated; and the patient may soon lapse into the condition, described above, of constitutional infection. The pustule does not apparently always present this typical appearance; when occurring upon the hands such appearance is uncommon. It has then no central black eschar, no raised vesiculated border. It is described as "a small, slightly inflamed tumor, exuding only serosity; giving rise to comparatively little pain or even increased sensibility, but showing a tendency to set up a diffuse cellulitis." Constitutional infection may follow.—*Med. Times and Gazette*, July 21, 1883.

Action of Alkalies on Bile.—Lewaschew and Klikowitsch have recently made interesting experiments to determine the action of alkalies on the composition of the bile. Dogs, with fistulæ leading to the gall-bladder, were used but no canula was inserted. The animals were deprived of food and drink for twenty-four hours previous to the experiments. From these experiments it seems that artificial and natural waters have a similar action on the biliary secretion. The quantity of bile flowing from the fistulæ was diminished for some time after the administration of an alkaline water, an effect probably due to an increased flow of bile into the intestines. After this, however, the amount flowing from the gall-bladder rose above normal. The quality of the bile was the same whether artificial or natural alkaline waters were used, but with waters of different degrees of concentration, different results were obtained. The effect of carbonate of sodium on the composition of the bile was more rapid, lasting, and powerful than that of sulphate of sodium. Weak solutions were more powerful than strong and highly concentrated solutions. Consequently the mineral waters whose chief constituent was carbonate of sodium had most influence on the composition of the bile, and especially if the carbonate was not present in a highly concentrated form. The effects were earlier and more marked as the temperature of the waters ingested was raised.—*Centralbl. für klin. Med.*, July 7, 1883.

Treatment of Yellow Fever.—M. de Lacaille, of Rio de Janeiro, has recently sent a communication to the Academie des Sciences relative to the successful treatment of yellow fever by carbolic acid and carbolate of ammonia. He also stated that attempts had been made to vaccinate with a weakened ferment, presumed to be derived from the yellow-fever fungus.

Resection of a Pulmonary Lobe.—Prof. Ruggi, Surgeon-in-Chief to the Maggiore Hospital, at Bologna, recently resected the superior lobe of the right lung and a portion of the middle lobe in a woman, æt. 31, 31, for phthisical ulceration. Thirty hours after the operation the patient was in a wonderfully good condition.

DIMINUTION OF THE RED GLOBULES OF THE BLOOD DURING THE ADMINISTRATION OF IODOFORM.—From experiments made on rabbits and from observations on syphilitics, HOFFER concludes that: 1. Rabbits lose weight, and show diminution in the number of the red blood-corpuscles during the internal administration of iodoform. The variations observed correspond to the alternations of suppression or administration of the drug. 2. Hypodermatic injections of iodoform in syphilitics, is often followed by anæmia. The specific manifestations were at the same time subdued by the use of the drug.—*Gaz. Hebdom.*, July 20, 1883.

CASCARA SAGRADA IN CONSTIPATION.—MR. R. A. DOUGLAS LITHGOW, in stating his experience with cascara as a purgative, says: Cascara sagrada seems to act as a tonic to the pneumogastric and sympathetic supplies of the *primæ viæ*, aiding the general processes of digestion, whilst especially promoting those of nutrition and assimilation. At the same time, it so influences the secretory system as to increase deficient, and to improve and restore vitiated secretions, by regulating the action of proximate visceral and intestinal glands. From this it will be seen that its use is especially indicated in cases characterized by torpidity of the liver and an atonic condition of the stomach and bowels.

Where habitual constipation depends upon derangement of the intestinal glands, with consequent defective or perverted biliary and intestinal secretions, associated with an adynamic condition of the muscular and nervous forces of the alimentary canal—involving congestion of the portal circulation, and also of the gastro-intestinal mucous membrane—the action of cascara sagrada will be found most satisfactory, and he has repeatedly known it to succeed in relieving and regulating the bowels when all the other usual remedies had failed.

He has seen no reason to withhold its use in any case of habitual constipation of a functional character, even in those occurring amongst children; but it must be admitted that it acts differently in different individuals, some requiring more, and others less; in some, occasionally producing griping pains, while in most cases its action is quite painless. Symptoms of tenesmus can be readily obviated, however, either by limiting the dose or by combining some suitable antispasmodic with the active agent.

In the numerous cases in which chronic constipation is associated with hæmorrhoids, cascara sagrada is of especial service, as its efficient action as an aperient relieves the venous congestion; whilst, instead of irritating, as many cathartics do, it seems to exercise a soothing effect upon the rectal mucous membrane.

With regard to the dose and mode of administration, the physician should exercise some discretionary power in suiting the remedy to the morbid condition, and in combining it with such other remedies or adjuvants as may seem desirable. In our opinion small doses, frequently repeated, will be found more satisfactory than large doses; and this is what we might naturally expect from the physiological action of the drug. When chronic constipation is complicated with flatulent dyspepsia, deficient gastro-intestinal secretion, and impaired muscular tonicity of the bowel, ten to fifteen drops three or four times a day, either before, with, or immediately after meals, will be found to give the most gratifying results. Two to five drops may be given twice or thrice daily to children of a month old. Except in one case, in which an overdose had been taken without medical sanction, I have never known cascara sagrada to produce any undue local or systemic disturbance, such as nausea, tormina, impaired appetite, or eructations; and, in fact, I know of no therapeutic agent which is altogether so reliable and satisfactory in the numerous class of cases to which I have alluded.

Ten or fifteen drops should be taken regularly twice or thrice daily for a week, after which time, if no material improvement has been effected, the dose may be increased until the bowels have been freely relieved, when it may be gradually decreased in amount and frequency until healthy intestinal secretions and increased peristaltic action have restored the alimentary canal to its normal condition. Lactopeptin, dilute hydrochloric and nitric acids, tincture of nux vomica, liquor strychniæ, glycerine, extract of malt, aromatic syrups, etc., may often be advantageously combined with the cascara sagrada, according to circumstances.—*British Medical Journal*, July 14, 1883.

EXPERIMENTAL INHALATION-TUBERCULOSIS.—DR. A. WEICHSELBAUM, after a number of experiments on this subject, thinks that the results obtained by previous experimenters are partially correct, and draws the following conclusions: 1. The inhalation of tuberculous sputum produces in dogs a true miliary tuberculosis of the lungs and frequently of other organs (bronchial glands, kidneys, etc.), but which seems to have no progressive character. 2. The inhalation of other organized though non-tuberculous substances may produce nodules in the lungs, which may, it is true, have the external signs of tubercles, but which cannot be positively identified as tubercles. In view of these results, he recommends as a precautionary hygienic measure, that the rooms in which phthisical patients are confined should be regularly and periodically ventilated and disinfected, and that the sputa should always be disinfected and removed.—*Medizinische Jahrbücher*, 1883, Hft. ii.

CYSTS OF THE URACHUS.—DR. J. B. WUTZ has recently contributed an elaborate paper on the urachus and cysts of the urachus, in *Virchow's Archiv*, Bd. xcii. Heft 3. The paper is based upon reported cases, personal examination, and study of the literature of the subject. With regard to the urachus itself, after seventy-four post-mortem examinations, Wutz draws the following conclusions: 1. A probe can be passed from the bladder into the lower part of the epithelial canal of the middle ligament of the bladder. 2. Probing is rendered difficult at the entrance of the urachus by a small cross-fold, which also prevents the penetration of fluids during life. 3. The diameter of the epithelial canal diminishes at the upper end, as does the muscular layer. 4. A muscular layer is always present above the epithelial tube. 5. The beginning of the tendinous character of the middle ligament of the bladder corresponds, as a rule, in children to one-half, and in adults to one-third the distance from the umbilicus to the vertex of the bladder. 6. In extra-uterine life there is a growth both of the muscular layer and of the epithelial canal.

He then considers both small and large urachal cysts and draws the following conclusions: 1. All observed cysts are situated in the lower third or fourth of the distance from the umbilicus to the summit of the bladder, and arise from the normally persistent portion of the urachal canal. 2. The majority of the cysts contain strata of pavement epithelium; some contain only a single stratum. 3. All the cysts have a covering, more or less developed, of smooth muscular fibres. 4. Their size varies from that of a microscopic object to that of a bean. 5. Concretions seldom appear in the urachal canal or in the cysts; those observed by him were composed of carbonate of lime contained in an organic substance. 6. Cysts of the urachus may become the seat of an inflammatory process.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, AUGUST 11, 1883.

YELLOW FEVER.

THE efficacy of a systematic effort to keep yellow fever out of the United States by a combination of the resources of the General Government with those of individual States is now being tested, and the results will be observed with interest, not only by physicians and sanitarians, but by all who are affected directly or indirectly by quarantine regulations. As matters now stand, however, at New Orleans, it is not quarantine which is being tested, but non-intercourse, which is a very different thing. By request of the State Board of Health, the Governor of Louisiana, in a proclamation dated July 24th, orders and directs that all vessels from Vera Cruz, Rio de Janeiro, Havana, and such other ports as may become infected with yellow fever, be prohibited from entering the waters of the State of Louisiana.

Evidently the Louisiana State Board of Health are unwilling to rely on their quarantine system, and are returning to mediæval methods. Nothing is said in this resolution, or in the proclamation of the Governor, as to where the infected vessels at the New Orleans Quarantine Station are to go, but it certainly could not be intended to merely drive them to sea without making any provision for the care of the sick or furnishing hands sufficient to navigate the ship, and it is probable that the proclamation has been issued with a tacit understanding on the part of all concerned that the infected ships are to go to Ship Island for treatment. It will no doubt be remembered by our readers that the previous opposition to that institution was mainly personal to the National Board, or to its New Orleans representatives.

Mean time, yellow fever has increased as usual in Cuban ports with the approach of warm weather, and in June it broke out with more than usual severity at Vera Cruz. Several ships from the latter place having yellow fever on board have arrived at Gulf ports, and have been sent to Ship Island, where four or five are under treatment at the present time. One infected steamer from Vera Cruz entered Chesapeake Bay, and another vessel having cases of yellow fever on board is at the quarantine station of Philadelphia. At the time of writing this, it is not known that any case of the disease has occurred this year in the United States, except at quarantine stations, and the season is now so far advanced that the danger of any extended epidemic this year is comparatively small. Nevertheless, Yellow Jack is trying our doors and peeping in at our windows in a fashion which causes very uncomfortable sensations in the minds of many persons in the Southwest who have had personal experience of the results when he once obtains a foothold in a city in warm weather, and it will be the middle of September before all apprehension on this account will have passed away.

While there are still great differences of opinion as to the contagiousness of yellow fever, the means by which it spreads, its period of incubation, and the possibilities of so treating a vessel infected by it that such vessel may, after a short delay, be safely allowed to come into port, the weight of evidence is in favor of the system of inspection, isolation, and disinfection recommended by the National Board of Health, which is essentially that of the New York Quarantine Station. This rests on the belief that, while yellow fever is very rarely conveyed by persons, it may be so conveyed under certain exceptional conditions not yet understood; that its period of incubation is, in almost all cases, less than ten days; that a ship which is infected with the poison may be, by thorough cleansing and disinfection, rendered harmless with so great a degree of probability that she may be allowed to reenter the channels of commerce, and that, when so disinfected, the sooner she is allowed to receive cargo and proceed to sea, the better, because if any germs survive the cleansing process, every day's delay increases the development of the poison.

The fact that the progress of a yellow fever epidemic is limited by season makes quarantine precautions against it much more important and valuable than they are against those diseases not so limited, such as smallpox or cholera, for even if the disease finally breaks through the barrier, yet, as it increases in geometrical progression, every week's delay in its entrance which can be secured, is equivalent to cutting off a week from the epidemic when at its height.

We have no information as to whether any use is being made of the Sapelo Sound refuge station on the Georgia coast, but a United States quarantine has been established by the Treasury Department at the mouth of Chesapeake Bay: and Ship Island, lying a few miles off the coast of Mississippi, and belonging to the United States, was selected by the National Board of Health, and fitted up as a refuge station to which infected ships could be sent from any of the Gulf ports for treatment.

So long as Ship Island remained under the control of the National Board, the Louisiana authorities were bitterly opposed to its use, declaring that the New Orleans quarantine station, located on the Mississippi River about sixty miles below the city, was in all respects preferable to Ship Island as a place for treating infected or suspected vessels, and utterly refusing to either send vessels to Ship Island or to admit vessels which had been at Ship Island, until they had gone through the same quarantine formalities at the New Orleans station as if they had just come from Havana.

But on the first of July last, Ship Island with all its equipment, including hospital, storehouse, building for those not sick, disinfecting-house, and a small steam yacht, was turned over to the Marine-Hospital Service, to which the Secretary of the Treasury had decided to confide the charge of the epidemic prevention fund appropriated by Congress.

The Louisiana Board appears to be on very friendly terms with the Marine-Hospital Service, and quite willing to coöperate with it, and hence, perhaps the non-intercourse proclamation above referred to may be considered as a round-about way to obtain the benefits of the Ship Island station without directly acknowledging that the means provided by the National Board at that point are being utilized. An inspection service is being maintained on the Mississippi River under the direction of the Sanitary Council of the Mississippi Valley, but if New Orleans is going to maintain non-intercourse, this inspection seems hardly necessary, so far as yellow fever is concerned, although it is no doubt useful, as tending to secure a greater degree of cleanliness on board the boats than would otherwise be obtained.

Upon the whole there is a fair prospect that we shall escape a yellow fever epidemic this year, and shall gain some experience which will influence Congressional legislation upon national health matters of which there is urgent need, and which will be attempted next winter.

THE REMOVAL OF NEOPLASMS OF THE BLADDER.

In two communications, made during the current year to the Royal Medical and Chirurgical Society, Sir Henry Thompson recalls attention to a class of cases which long experience has demonstrated almost invariably prove fatal unless subjected to surgical interference. Eliminating two operations for villous carcinoma, which, for obvious reasons, should not be tampered with, but of which one was removed and recurred, and one died, Sir Henry's ten cases show six recoveries and four deaths. Of the former, two were permanent after the first operation, two were permanent after a second, recurrence ensued in one case, and in one the growth could not be entirely removed. Eight of the operations were practised on males, with five recoveries and three deaths; two were performed on females, with one recovery and one death. These results, indicating, as they do, forty per cent. of cures, are highly gratifying, and clearly warrant the repetition of the operation.

Up to the present date, at least fifty-one operations have been practised for the removal of vesical tumors, of which thirty-three recovered, and only eighteen, or 35.29 per cent., died. Of the entire number, twenty-five were performed on males, with sixteen recoveries and nine deaths, and twenty-six on females, with seventeen recoveries and nine deaths. In twenty-two of the former the neoplasm was removed by perineal cystotomy, with seven deaths, or a mortality of 31.81 per cent; while epicystotomy was attended with two deaths in the three cases in which that procedure was resorted to. In twenty of the cases occurring in females, riddance was effected after previous dilatation of the urethra, with the result of fourteen recoveries and six deaths, or a mortality of 30 per cent., and in six the urethra or vesico-vaginal septum was incised, of which three, or 50 per cent., died.

In the male, Sir Henry Thompson opens the membranous urethra through a limited incision of the perineum, and dilates the prostatic urethra and neck of the bladder with the index finger. In the female, the urethra is rapidly dilated with the finger; while in either sex the tumor is removed with forceps of various sizes and curves. Against these exclusive modes of operating we must enter a most decided protest. The essential portion of the procedure in either sex is dilatation of the urethra and neck of the bladder, so that the opening must, of necessity, when the tumor is large and firm, be insufficient to permit of extraction, while the risk of lacerating the bladder is greatly enhanced—an accident which happened to Sir Henry and Von Langenbeck in attempts to tear away the tumor with the forceps. Excepting in the case of pedunculated growths, the forceps are almost worthless from the impossibility of getting rid of the entire mass, a consummation which Sir Henry does not, however, consider necessary, as he states that "cicatrization often leads to contraction and consolidation of the remainder;" a theory that is disproved by his having been obliged to operate a second time on two of his cases, not on account of recurrence, but simply from the fact that the first operation was not thorough.

The so-called papillomata, which constituted the majority of his cases, are in reality papillary or villous fibromata, the villi containing fibrous tissue continuous with that of the mucous or submucous connective tissue. To remove such a growth effectually, it will not suffice to crush and tear away the tufts, the base of the tumor must be attacked, and we know of no instrument so well adapted to the purpose as the sharp spoon or a sharpened lithotomy scoop. With the former of these contrivances, Simon, of Heidelberg, and others have safely and successfully attacked these growths, even when they filled nearly two-thirds of the female bladder. In multiple polypoid fibromata the scissors are far less dangerous than the forceps; and it is interesting to note that they were first employed by Cross, of Norwich, after a preliminary perineal cystotomy, nearly fifty years ago.

In conclusion, we may be permitted to express our conviction that, in the male, large sarcomatous, fibromatous, and myxomatous growths should be reached from above the pubes, while smaller growths should be removed with the forceps, spoon, or serre-nœud, after a median or lateral perineal cystotomy, the operation selected depending upon the size and configuration of the neoplasm. In the female, on the other hand, papillary tumors should be scraped away with the sharp spoon through the dilated urethra, epicystotomy or colpocystotomy being reserved for large and solid growths, the latter operation being the preferable one, as the interior of the bladder can be inverted through the wound, whereby the removal of the mass is rendered a comparatively simple procedure.

"THE ALIPTIC ART." IS IT A LOST ART?

The ingenious paper presented in another column, on "the aliptic art," can hardly be regarded as heralding a revival of an extinct process. The historical facts which Dr. Peterson has collected show a continuous succession in the published records reaching down to our own day. The expedient is novel only to those who have for the first time become acquainted with its actuality.

There is a clear, a most necessary distinction between oil inunctions and massage. The use of oil is a mere refinement in the application of massage, and when oil inunctions are required, massage does not form a necessary part of it, may often, indeed, be inadmissible. In some cases the two methods are conjoined.

From the merely therapeutical point of view oil inunctions serve two distinct purposes—to affect the condition of the skin itself; to modify the functions in general. Oil inunctions in febrile diseases, scarlet fever, for example, have a distinct effect on fever heat, reducing it sensibly. We need at the present time some exact observations showing the degree and duration of this influence. Oil inunctions are much employed now to improve the nutrition of the body in general. That this result follows is an undoubted fact. The oil disappears in the course of the frictions, the body gains in weight, and oil globules are found in the feces when there was no other source for their appearance there.

Massage, as now understood, is a part of that method of systematized movements commonly known as the Swedish movement cure. This consists in rubbing, kneading, and exercise of individual muscles and muscular groups, and movements of joints. In its present form, massage is a comparatively modern art.

Dr. Peterson, we fear, is much too sanguine in supposing that the "aliptic art" will be so far utilized as to make the skin the medium for the introduction of medicaments into the system to any large extent. The epidermis offers too substantial an obstacle to be overcome readily, unless by persevering friction, and its removal is a painful process. Notwithstanding its undeniable efficacy, the inunction treatment of syphilis has not been popular. Patients shrink from the labor required, and are afterward tormented by the sense of a filthy skin. Few adults are willing to undergo the application of oil inunctions, when suffering from wasting disease, in which they are highly beneficial, and children usually rebel energetically unless too ill to remonstrate. There are other more facile and efficient methods of introducing medicines into the circulation, so that the aliptic method will rather decline than advance in professional esteem. Such is our conviction. The expression of this, however, does not interfere with the instruction and entertainment afforded by a perusal of our contributor's excellent paper.

REFLEX NASAL COUGH.

In the American Journal of the American Sciences for July, Dr. John N. Mackenzie, of Baltimore, Md., has called attention to a cause of reflex cough, the frequency of which, according to his observations, makes it a matter of no small importance, and demands for it, therefore, general notice.

Dr. Mackenzie's attention was first directed to the study of "nose cough" by the fact that during the application of instruments, probes, etc., to the nasal mucous membrane, paroxysms of coughing were often excited which continued until the instrument was removed. The cough varied in character from a succession of short expiratory acts to convulsive paroxysms which interfered greatly with instrumentation.

Dr. Mackenzie then instituted experiments upon patients, upon friends, and upon himself, in the course of which he ascertained that the susceptibility was confined to the turbinated body, and particularly to the posterior end of the inferior turbinated bone, and the portion of the septum immediately opposite. This being the area occupied by the erectile tissue of the nose, he naturally concluded that this structure was connected in some way with the production of the reflex operation, and associated with its physiological function, whatever that may be. Of course, various degrees of susceptibility were observed. They have their parallel in the reflex asthma from polypi and chronic nasal catarrh.

Thence Dr. Mackenzie passed to clinical observation, and he reports not less than seven cases of cough associated with morbid states of this area and otherwise inexplicable, which responded promptly to operative and other topical treatment. All were cases involving decided hyperæmia of the mucous membrane of the area referred to, with or without coincident hypertrophic thickening. Doubtless, many men of large experience will recall cases of obscure cough, which may have been explained by the information contained in this article.

Dr. Mackenzie says these facts are the result of personal experience, and, as they represent the result of solitary observation are, of course, open to correction. Doubtless they will soon receive the test they will be required to bear, because the number of capable workers in this department is now so large that in almost every city two or three observers will be submitting them to test.

THE JOHNS HOPKINS SCHOOL.

DR. JOHN S. BILLINGS has declined the offer of the Professorship of Hygiene in the Johns Hopkins University, for the reason that it is impossible for him to hold this place while he is an officer of the army, and he prefers to retain the latter position and continue his library and indexing work, for the present at all events. It is probable, however, that in the course of the coming winter he will give a course of lectures at the University on the subject of municipal hygiene.

The object of the University authorities in appointing Professors Remsen and Martin, and Dr. Billings, to Chairs in the Medical Department, is understood to be for the purpose of obtaining a nucleus for the organization of the Medical School, to which additions will soon be made, and to have the benefit of their conjoint advice as to the best course to pursue, rather than to have them commence at once systematic instruction in the branches to which they were assigned. The organization must be somewhat of a temporary character until the relations which are to exist between the Hospital and the Medical School are determined on, and the Hospital itself is ready for work or very nearly so. As Dr. Billings takes great interest in both the Hospital and the proposed Medical School, and is well acquainted with the condition and requirements of both institutions, it is certainly very advisable that his counsel should be obtained, and no doubt it will be obtained; in which case his declination is merely that of the formal title of professor, while he can still render the most important of the services which the University at present requires.

The profession will be very glad to know that Dr. Billings' connection with the army and the medical library of the Surgeon-General's office is not to be severed for the present, at least. The library will always remain his most enduring monument, and he ought certainly to finish the *Index Catalogue* before undertaking any other work which would interfere with it.

At the same time it must be admitted that the proper organization of the Medical Department of the Johns Hopkins University is a very important matter to the medical profession of this country, since it is likely to very considerably affect the future of medical education and medical science in the United States, and to this end the University should secure the best men for its work, but it seems to us that it ought to be, not only possible, but easy to effect some arrangement by which the University can have the benefit of Dr. Billings' experience and knowledge, and still not interfere with the work which he is doing for the medical profession of the whole world, by making its literature accessible and usable.

THE CHOLERA EPIDEMIC.

THE mortality reports from Egypt during the past week have been very incomplete, and daily returns from the principal cities are no longer forwarded. The number of deaths, although diminishing, is still large, but the disease is not so virulent as it was, and a greater proportion of cases recover. On August 2d, the total mortality from cholera to date was given in a dispatch from Alexandria as 11,000, but the London *Daily News* asserts that it amounts to 16,000.

The disease appears to have extended beyond the limits of the delta of the Nile. It has obtained a foothold in Alexandria, although, if the dispatches are to be relied upon, it is not making any headway there. It has appeared at Beyrout in Syria, and has extended into Central Egypt, where 103 deaths were reported in the Province of Beni-Souef on August 3d and 4th.

Whether the disease be true Asiatic cholera, or some "malignant local distemper," matters little to us, since it has spread beyond the unsanitary localities in which it first appeared, and has attacked Europeans in Cairo and Alexandria, while the British army can number its one hundred and ten victims up to the 6th inst. A disease which causes the death of over 500 persons a day in the city of Cairo, and appears to be gradually penetrating the adjacent country, is one to be equally dreaded with the cholera, and every precaution should be used to keep it at bay.

Apropos of the letter in a recent issue on the prophylactic treatment of diphtheria, suggested by Dr. Porcher some weeks since—namely, by tincture of the chloride of iron, chlorate of potassium, and quinine—an experience which has come to our knowledge may be mentioned. In a family under medical observation, two fatal cases of diphtheria had occurred. Of three children at the time unattacked, two took willingly a large number of sugar-coated quinine pills, of which a bottle happened to be in the house. A third child could not be induced to take any whatever. The latter soon took diphtheria, and died after a short illness. The remaining two escaped the disease.

REVIEWS.

Early Aid in Injuries and Accidents. By Dr. Friedrich Esmarch, Professor of Surgery at the University of Kiel, etc. Translated from the German by H. R. H. Princess Christian. Philadelphia: Henry C. Lea's Son & Co., 1883. 8vo., pp. viii. 117.

Professor Esmarch's book on emergencies is a new illustration of the fact that eminence in one domain is not always a guarantee of fitness for another. That, besides securing a wide circulation in Germany, it has been translated in England by H. R. H. Princess Christian, and reprinted in this country by one of its foremost publishing houses, is rather an evidence of a somewhat indiscriminating hunger for such a work than of its satisfying qualities. The greatest respect for its distinguished author cannot blind the critic to the fact that this production is unworthy of his reputation. It is marred by commonplace, inequality, vagueness, and even occasional error. It opens with an introductory lecture on anatomy and physiology, in which the reader is informed, on one page, "of the limbs; . . . of these there are two upper and two lower—the arms and the legs;" and fifteen or sixteen lines more in which absolutely no other information is conveyed than the *number of bones* in their different parts. On another page we are told that the system must get rid of "water and urea." This is followed by seven lines on the kidneys, which contain only a fair description of their usual shape, and a very uncertain one of their situation. In speaking of the circulation, the author informs us that if the movement of the heart is arrested, it "stands still, and death soon follows." On the other hand, he gives the shape, size, and number of the red corpuscles; while this whole section contains not a word about the situation of the principal arteries and veins. Turning to the lecture on "Injuries," we read that "contusions are injuries caused by falls or blows which have resulted in internal lacerations, particularly of the smallest blood-vessels." How many examiners in surgery in America would accept such a definition from a student? Or who would affirm in general terms that "in injuries to lungs you have blood-spitting?" As to treatment, patients with severe contusions, pale and faint, are to be sprinkled with cold water; the surgeon closes wounds "*either* [italics ours] by stitches or a bandage (*not* by means of sticking plaster; this, like most salves and plasters, belongs to the surgery of the middle ages)." (!) Think of a German policeman trying to close a wound with stitches! Think, too, of the horror of sticking plaster being capped with a horror of germs—for Esmarch is a Listerite of the most infantile faith, and instructs his hearer, *in emergencies*, be it observed, to use antiseptics.

In treating of hemorrhage, the author gives the situation of arteries in only three places—the upper part of the thigh, the upper arm, and the neck above the collar bone. "It is at these points," he adds, that a surgeon generally applies pressure (as with a tourniquet) when he wishes to stop hemorrhage." Is it captious to inquire whether German surgeons use tourniquets to the neck?

But, to unbend—of burns: "In general, women are more careless about fire than men. How often are the light clothes of ladies set on fire by the careless handling of lighted candles, lamps, etc." The author thinks it ought to be stopped. "But many, alas! remain silent, and go their own way, like the priest and the Levite, and excuse themselves by saying, 'what does it concern me? Let every one take care of himself!'" He advises ladies to have the light material of ball-dresses rendered incombustible, and pictures the scene of a burning thus: "Flames envelop [*sic*] the unhappy creature, scorch her arms and hands, her neck and face; her hair and cap blaze up." She ought to throw herself on the ground and roll about, he says; but as this is not customary with ladies whose hair and caps blaze up (in America most women get burned at the lower extremity), the bystanders should surround her with a rug or coat, throw her on the ground, and "*roll her about there till the flames are put out.*" But why this rolling about? Is there no more orderly and composed way to smother flames? But, it is to be feared that they are likely to be precipitate in Germany; for the author says, "should any one have fallen into a lime-kiln or soap-lye, he should be drawn out as quickly as possible." And Her Royal Highness lets this advice go without comment.

But we may not linger over all the unintentional humor of this book. Nevertheless, we cannot keep back from our readers the caution, that persons to be revived from freezing "should be carried carefully into a closed but cold room, and undressed with care, *for fear of breaking the stiffened limbs.*" Afterwards, they may be rubbed with cold cloths, cold sand, (!) or put into a cold bath; part of which seems rather rough therapeutics, while all of it is false in principle, as experience and experiment in Russia has fully shown.

With little space left, after so long a justification of our before-expressed opinion of this little book, we can only say, on the other side, that it contains many excellent suggestions and a number of instructive woodcuts. But, as a whole, it is very far from what the world has a right to expect of such a man as Professor Esmarch, as well as from what the world needs in a book on accidents.

SOCIETY PROCEEDINGS.

THE PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday Evening, June 14, 1883.

The President, James Tyson, M.D., in the Chair.

KIDNEY AND HEART FROM A CASE OF CHRONIC BRIGHT'S DISEASE; EXTREME URÆMIC DYSPNŒA; MARKED ŒDEMA; RELIEF TO BOTH BY ACUPUNCTURE; INCIPIENT NEURITIS.

Dr. J. H. Musser, in presenting the specimens, gave the following clinical history:

R. T., æt. 35, admitted to University Hospital July 17, 1878; single; a patcher of goods; frequently exposed to draughts while in profuse perspiration; used tobacco to excess; once or twice a year he would "spree;" at twenty-two he had a chancre (?); no secondary symptoms; three times he had gonorrhœa; always healthy prior to present illness; never had rheumatism.

The patient inherited a tendency to phthisis from both parents, and to rheumatism from his maternal grandmother.

The first of the present illness was observed two years ago by a sudden night attack of dyspnœa. The dyspnœa continued for nine weeks, worse at night, and preventing work in the daytime, œdema of the feet and frequent micturition accompanying the dyspnœa. He improved, to have a relapse in four weeks of a month's duration, followed again by temporary improvement and a third relapse. From the latter he never rallied, œdema, cough, dyspnœa, frequent micturition, and dyspeptic symptoms being constantly present. The cough was dry, and attended with subintestinal pain. The œdema was general. When admitted to the hospital, under the care of Prof. Pepper, his condition was as above mentioned. During the July, August, and September following, the asthmatic attacks continued. In October, they were relieved, but the anasarca became more pronounced.

It may not be out of place to say that the dyspnœa was very severe, and almost defied treatment. It presented the clinical characters of uræmic asthma, and was relieved only by inhalations of nitrite of amyl or by hypodermic injections of morphia. The anasarca was very great and was not relieved by diuretics, diaphoretics, or cathartics. In October, acupuncture was resorted to, with temporary relief to the lower extremities and scrotum, its good effect lasting five days only, but being so marked as to encourage one in its use. During the following three months the punctures were made about fifteen times, and after each operation about three pints of serum would drain away. In the latter part of December, erysipelatous inflammation developed about the punctures, and extended over them. During the progress of the inflammation, large bullæ would form, the bursting and continued free discharge of which caused an entire disappearance of the œdema of both legs. Relief was not only afforded by these operations to the œdema, but the attacks of asthma notably diminished in frequency and severity. On January 8, two weeks after the inflammation of the right leg developed, sloughing took place. The sloughing was confined to the calf of the leg, was deep, and was attended with free serous discharge from the ulcers. In a few days, a low typhoid state set in; he rapidly lost strength, and on the 7th of February died of exhaustion.

When these notes were taken (January 8), the remaining features of the case were as follows: He was emaciated and anæmic, and his skin was harsh and dry; his countenance anxious; appetite poor; flatulent dyspepsia marked; the bowels constipated; hemorrhoids; tympanitic abdomen; slightly enlarged liver; normal spleen. At the apices of the lungs, diminished expansion; flattening, impaired resonance, and increased fremitus at the left; moist, crackling, and subcrepitant râles heard throughout the lungs. Apex-beat of heart in sixth interspace one-fourth inch inside of nipple line; veins of right side of neck enlarged; cardiac impulse moderately strong; at apex a low-pitched systolic murmur; muscular element lessened; at base, pulmonary second accentuated. The width of the cardiac area of dulness was increased one-half inch to the left, and was not changed by full inspiration.

Urine contained albumen; amount varying, at times two-thirds then one-third. Hyaline and numerous granular casts.

Opthalmoscopic examination. Small disks. Myopia. O. D. disk dirty-gray, veins tortuous. No marked change in the color of the nerve—outlines misty and it slightly swollen. O. S. disk same, but more marked. No hemorrhage in either eye. Diagnosed incipient neuritis.

Autopsy, five hours after death. No rigor mortis; emaciated; commencing ecchymoses. Great fulness of the venous circulation.

Lungs: apices bound down by adhesions. Slight right hydrothorax. Base of left lung anteriorly and posteriorly adherent. At left apex three or four areas of catarrhal pneumonia.

Heart: weight twenty-one oz.; left ventricle wall hypertrophied; mitral valve insufficient, admitting almost three fingers; its cusps thickened; one leaflet of the aortic valve slightly diseased; left cavities increased in size. Aorta atheromatous, a large patch especially one-half inch from the valves.

Liver enlarged, hard, congested. Kidneys small, congested, capsules adherent, relation of cortical to medullary substance normal.

Microscopical examination. Kidneys showed decided interstitial nephritis with fatty degeneration of the tubular epithelium. Liver slightly cirrhotic and fatty. Muscular fibres of the heart slightly undergone fatty degeneration.

AORTIC VALVE DISEASE DUE TO THE COMBINED ACTION OF STRAIN AND RHEUMATISM—EXCESSIVE DILATED HYPERTROPHY.

Dr. J. H. Musser, in presenting the specimens, said that neither the habits, the hygienic surroundings, nor the social condition of Mr. C. K., from whom these specimens were removed, had any relation to the cause of his illness. As a laborer in a rolling mill his occupation might have had some predisposing influence on the localization of the diseases, he being exposed to extremes of heat and obliged to do heavy lifting. The family history did not disclose hereditary disease. Withal, in the past twenty years—at this noting he was aged forty-seven—he had had frequent attacks of inflammatory rheumatism, and in 1878, four years previous to this account he had an unusually severe attack, after which he recognized his present palpitation, and of indigestion characterized by pain and vomiting. These symptoms increased in frequency and severity, and were often attended by œdema of the legs. The last three years he was unable to work. Within the year he lost in flesh and strength, and had several attacks of pulmonary congestion.

His condition when in hospital, December, 1879, was as follows: Slightly emaciated; sallow complexion; anæmic appearance; continuance of suffering, dry skin; cold extremities; ankles œdematous; muscular weakness, tremor on exertion; marked prominence of lower part of chest and bulging of process; sternum pushed forward, lower half especially, giving pointed, pigeon appearance; impulse marked in normal cardiac area, and extending two inches to the left; epigastric pulsation; pulsation of veins of neck; apex-beat in sixth interspace one inch outside of nipple line; no hepatic pulsation. A line drawn diagonally from the second right costo-sternal articulation to the fourth rib, one inch from right nipple line, and then vertically to the hepatic dulness, represents the right border of cardiac dulness. From the top of the third left rib, one inch from the sternum, a uniformly curved line extending from the apex-beat, showed the left limit. By joining these lines with horizontal ones, the upper and lower borders are defined.

On auscultation at the aortic orifice a strong systolic murmur, transmitted to the vessels of the neck, and a rough diastotic murmur, transmitted to the base and along the sternum, are noted. At the xiphoid cartilage and at the apex systolic murmurs, differing in pitch, are heard, the latter also at the spine of the left scapula. Pulse small, feeble, compressible, not 60.

Cough, muco-purulent expectoration are complained of, and the physical signs of bronchial congestion are observed. The appetite is poor, pyrosis and flatulence distressing, bowels constipated, urine slightly albuminous, no casts.

A subsequent course with calomel and soda and a liquid diet at first, followed by digitalis and quinia, the venous stasies now disappeared and the cardiac symptoms ameliorated within a month. After exposure to cold, internal venous congestions and œdema now supervened, and in five days, January 20, 1879, he died of pulmonary congestion.

At the autopsy the lungs, liver, spleen, and kidneys were found characteristic of dilatation of the heart—congested and with increase of connective tissue in the latter three organs. The heart presented very interesting lesions. It was enormously enlarged, weighing thirty-two ounces. The right heart was dilated; the ventricle wall averaged one-eighth of an inch in thickness; the tricuspid orifice was insufficient and admitted four fingers. The left ventricle wall averaged one-half inch in thickness; the mitral valves were slightly thickened, and a few opaque patches were seen. The aortic valves presented a remarkable appearance. Two of them were fused together and were rigid, projecting in the lumen of the orifice. The other valve also assisting in narrowing the calibre of the opening by rigidly jutting outwards. The lumen was scarcely more than a slit. The coronary arteries were not closed, and were found at the bottom of pouches with calcareous walls. On one side the deposited calcareous matter, of which the valves were composed, extended under the periendocardium to the base of one of the mitral leaflets. Of course the valves were covered by endothelium.

It is of interest to note that the mitral valves comparatively escaped the inflammatory storms, while the aortic valves were so markedly affected—contrary to the usual rule. It is suggested that a chronic valvulitis, or at least hyperæmia, might have been started by the strain incident to his occupation, and hence the valves readily invite acute inflammatory processes, the present case being a secondary degenerative result thereof.

CORRESPONDENCE.

LETTER FROM PRAGUE.

Climate—Food—Detachment of the Heart by a Crush, without External Wound—Sudden Death in Rheumatism—The University Examinations.

The last three weeks here the weather has been extremely warm, the thermometer running up sometimes as high as 33° or 34° C.; but, judging from what the papers say of the hot spell in New York, 34° C. would be considered rather pleasant there. We have the advantage here, however, of cool nights, no matter how hot it has been during the day.

One misses ice-water and our various cooling appliances very much; it is possible, with a good deal of trouble, to get a glass of water with a few pieces of dirty ice in it, but it always seems to excite so much surprise, alarm, and horror in the spectators that one has to seek out a secluded corner of the restaurant to drink it. I do not know which they regard as the worst, drinking ice-water or eating raw tomatoes. Now, I am very fond of the latter, and always eat them when I can; but from seeing a crowd around my part of the room every day, I begin to have some suspicion that the proprietor uses me as an advertisement, and that crowds come daily to see the great American tomato-eater. Ice-water especially seems to be regarded as a deadly poison, the cause of all the dyspepsia in America.

It is a fact that we do have more dyspepsia than the people here; but I think it is due rather to the quantity of food we take than to the nature of it. For many reasons, the quantity taken here is limited, the chief being that everything is so badly prepared that no living man could eat what we would call a respectable meal; then also the habit of paying separately for every individual thing one eats, even to the bread, is not conducive to a large appetite.

The ordinary midday meal here for the better classes is about as follows: First, a soup which has a whole legion of names, which are given to it according as to whether it contains sausage, potatoes, liver, or some other abomination, the body always remaining beef soup. This soup is on the whole not very bad. Next comes the inevitable "Rindfleisch," the boiled meat from which the soup has been made, a dark, dry-looking substance, easily chewed, but, as all the salts have gone over to the soup, having absolutely no taste, it is easily digested, and, though not palatable, is perhaps as nourishing as any other meat. Next comes the "Braten," and a glow of satisfaction comes over the face of the diner, for he has eaten his "Rindfleisch" to live, and now lives to eat his "Braten." This consists of baked or, more generally, fried veal or pork, and is served swimming in gravy and onions. A salad, made either of lettuce or cucumbers, which have been soaked in salt water several days to take all the colic out of them, is generally eaten with this. After this comes the dessert or "Mehlspeise," which may consist of anything in the world, provided we exclude all that is good. With this dinner a quart of beer or a pint of wine is generally drank.

You see by this that the most fertile source of dyspepsia, overloading the stomach, is practically excluded. Possibly another thing which helps to keep the eater braced up is that he eats everything with his knife, and in this way must take a not inconsiderable amount of iron into his system. True dyspepsia is a very uncomfortable and uninteresting disease, but, even if we were obliged to get dyspepsia from our manner of life, I do not know but that it is to be preferred to the German dinner. In some of the larger cities, where a higher degree of civilization has been reached, as in Vienna and Berlin, one can do better.

Strange to say, with the advent of the very hot weather, typhoid fever began to diminish, and now makes rather a small percentage of our post-mortems. In the past two weeks, we have had some rather interesting autopsies; one of these was a crushing injury, the man's thorax being caught antero-posteriorly between the bumpers of two cars as he was coupling them. Death was instantaneous. At the autopsy, no external injury was seen; several ribs on each side were broken, and the heart was found *free* in the abdominal cavity, it having been torn from its attachment to the great vessels and forced through a rent which was made in the diaphragm. It is rather difficult to understand how the violence could have acted so as to produce this result; most probably the man must have been stooping slightly forward when caught.

Another clinical case which came to autopsy a few days ago was also in many respects remarkable. The history of this was briefly as follows: A young man of twenty-two was brought into the hospital suffering from acute rhematism, high fever, swollen joints, etc. After a day or two symptoms of heart complication appeared, and the lesion here was referred by a clinician, one of the most careful and exact diagnosticians I ever saw, to the mitral valve. The patient improved under the usual alkaline treatment, and after being in bed two weeks made an effort to get up. He at once fell back in a state of semi-collapse, symptoms of acute peritonitis set in, and in two days he was dead. The diagnosis made was a most natural one; it was thought he had an inflammation of the mitral valve, and what was more natural than to suppose that an embolus coming from here had plugged up some large branch of the mesenteric artery. At the autopsy it was found that all the valves of the heart were free except those which enjoy almost an immunity from disease, the valves of the pulmonary aorta. Here one of the valves was ulcerated, a great rent was torn in it, and the blood had forced itself between the two lamellæ, giving rise to the so-called valvular aneurism. As was diagnosed, an acute purulent peritonitis was found, and the following condition of his intestines: The man had an abnormally long mesentery and S. Romanum. A large portion of the small intestine, about two-thirds of the ilium, was found twisted on its axis and twisted around the loop of the S. All circulation was cut off in both, and hence gangrene. This form of "Achsendrehung," in which a loop is formed which includes another portion of the intestine, is one of the rarest pathological conditions. Of course there was no connection between this and his acute rheumatism, and possibly none with his sudden collapse on rising.

Examinations are all over, and the University is practically closed for the summer, and the candidates have gone home happy or miserable, as the case may be. The examination given in pathological anatomy is not so difficult as I expected it to be, considering all the training the men have had. The candidate has to make an autopsy, and point out and explain all the principal changes; then he is given two specimens, usually easy ones, for microscopical diagnosis. This is the practical part, and in addition to this he is examined orally by the professor, some leading question being given him, on which he has to discourse for fifteen minutes. If a man fails in his practical examination he can have another chance after four months, if in his theoretical, after two months. The professor is rather lenient towards them; assuming 10 to be the highest a man can make, he is allowed to pass with 3 or 4, so that, in spite of the thoroughness of German teaching, a man can start on his medical career equipped with a very small stock of knowledge in the domain of pathology.

W. T. C.

PRAGUE, July 16, 1883.

A HEAD-SUPPORT FOR THE LARYNGOSCOPIC MIRROR.

To the Editor of THE MEDICAL NEWS.

SIR: In the number of your valuable journal for June 23d, I see that Dr. J. J. Chisolm, of Baltimore, describes under the head of "new inventions" an apparatus for securing the frontal mirror, which consists of a band running over the crest of the head, to one end of which the mirror is secured, whilst the other holds the instrument in place by compression of the occiput.

The device is an old one, and is familiar to those who pay special attention to diseases of the throat. In England, the occipito-frontal band is known as Johnson's, from Dr. George Johnson, of London, who claims to be its originator. The original apparatus has been variously modified, the most recent improvement being the jointed bar of Fox (optician), of Philadelphia, which was brought some time ago to this city and is in use in one of the special dispensaries. This method of securing the frontal mirror has, however, been almost universally discarded by specialists, and among them its inventor, in favor of the steadier and more portable silk head-band of Kramer, or the spectacle-frame of Semeleder.

The lenses behind the central aperture in the mirror used by specialists to remedy defective eyesight are objectionable in throat examinations, as they necessitate monocular vision. A much better plan would be to have appropriate glasses set in the spectacle-frame, after the manner used in the examination of the eye for errors of refraction.

Respectfully yours,
JOHN N. MACKENZIE, M.D.

BALTIMORE, July 29, 1883.

NEWS ITEMS.

NEW YORK.

(*From an Occasional Correspondent.*)

PROGRESS OF THE "NEW CODE."—In THE MEDICAL NEWS of July 14th, we gave some items showing the progress of the National Code movement. In the present, the doings of the "New Code" party will be briefly referred to. We have found it very difficult to obtain from the "New Code" men information other than that derived from the newspapers, in the way of editorial puffs of the "New Code," abuse of the National Code and its advocates, and sensational reports of "The Association for preventing the reënactment in the State of New York of the present Code of Ethics of the American Medical Association." This is the exact title of this association of medical men, who also style themselves the liberals, the progressives, and the gentlemen.

The following is extracted from the *New York Herald* of June 6th:

"The report of the liberals is a handsome quarto of ten pages." . . . "The total number of signers in the report is 1265, but it was understood several days ago that over one hundred more had subscribed, and the list has been increased since then. The total membership of the county medical societies is 3827, so that the liberals thus far have only captured a large one-third. They say that the old Code men have only obtained[1] *about six hundred* signatures up to date, and that the remainder are non-committal as yet." Only lately was it possible to secure a copy of the "handsome quarto" referred to in the *New York Herald* of June 6th A short analysis of its contents affords an insight into the way the "New Code" party canvass and count.

Their methods and their arithmetic are alike instructive and entertaining. Their committee work is done in formidable style. For instance, a committee of fifteen was appointed to draft a *declaration* of the views held by the opponents of the present Code of the American Medical Association. Then there was appointed or elected an advisory council of seventy-six members of the "Association for preventing the re-enactment, etc.," of the National Code, representing thirty-five counties. The meeting at which this "advisory council" was appointed, was held April 6, 1883, nearly four months ago. Great results were prophesied; and the whole State was to be forthwith carried by the promises of liberality, etc.

---

[1] The italics are our own.

It is now time to ask what results have been attained by this active work of the last few months. Their very best showing gives for the city and entire State of New York a membership of 729, of which (after careful comparison of all published lists of both sides) forty-one are found to have declared themselves as upholding the National Code, and one has died. This leaves the "Association for preventing the reënactment" of the National Code with a membership of 687, against 2256 for the National Code as published June 21st. The city of New York alone gave for the National Code 742, 55 more than the entire vote of the "New Code" party in the city and State. The whole vote cast in the city and State of New York appears to be 2943, of which the National Code got 2256, a majority, over the "New Code" of 1569, or more than three-fourths of the entire vote.

CHOLERA MORTALITY.—The mortality returns from Egypt are very incomplete. Reports have been received as follows:

Total deaths from cholera in Egypt,	August 1,	887
" " " " "	" 3,	870
" " " " "	" 4,	748
" " " " "	" 5,	501
" " " " "	" 6,	598
Deaths from cholera in Cairo,	July 31,	275
" " " "	August 1,	273
" " " "	" 3,	170
" " " "	" 4,	160
" " " "	" 5,	11
" " " "	" 6,	78
Deaths from cholera in Alexandria,	July 31,	3

In Cairo the weather is intensely hot, and the average temperature under canvas is 106°.

110 British soldiers have died in Egypt from cholera since the outbreak of the disease.

Three cases have been reported at Beyrout, in Syria, and the Turkish Sanitary Council has decided to establish a cordon around the town, and to quarantine all vessels from there for twenty days.

MEDICAL AID FOR EGYPT.—The Indian government has determined to send to Egypt seven doctors and forty assistants. Twelve English doctors arrived at Alexandria on August 2d, and at once proceeded to Cairo.

SURGEON-GENERAL HUNTER has been appointed by the British Government to make investigations regarding the cholera now prevailing in Egypt. He has had extensive experience with cholera during his service in India, and from his special and professional knowledge he is said to be well qualified to conduct the inquiry for which he has been selected.

M. JULES ARONSSOLM, Professor of Organic Chemistry in Paris, has also been sent to Egypt to study the cholera epidemic.

THE ORIGIN OF THE CHOLERA.—A letter just received by the State Department from the Consul-General at Cairo, Egypt, dated July 5, 1883, states that cholera first made its appearance in lower Egypt on the 20th of June, or rather was first made public at that date; that the constituted medical authorities pronounce it to be the true Asiatic cholera, but are unable to say how it first reached Damietta, though it is generally ascribed to the deplorable sanitary condition of the province. There exists a bovine disease (epizootic) in that province, and many cattle dying were thrown in great numbers in the Nile and various canals leading from it; that the inhabitants drink this contaminated water, and subsist largely on the flesh of these diseased cattle. This, taken with the fact that the abundant fruit of the country is used in excess, leads the medical authorities to think that the disease could only be expected. Three other towns near Damietta, viz., Mansurah, Serbin, and Samanoud, were also suffering with cholera at the date of the Consul's letter. The daily death-rate at Damietta was 157.

The Consul concludes by saying that the Egyptian government is taking active measures to interrupt communication between places suffering from the disease by establishing sanitary cordons and prohibiting the public sale of fruits, fish, and unwholesome meat in the infected districts.

THE DISEASE AT DAMIETTA.—N. E. Stevens, United States Consul at Smyrna, writes to the National Board of Health, under date of July 13th, as follows: "The news from Egypt is less alarming than at the time of my last report. Facts have come to light tending to show that the disease which is decimating the population of Damietta is not Asiatic cholera, but a malignant local distemper caused by the filthy condition of the town and the unclean habits of its lower classes, whose principal article of food is fish, caught from water polluted and poisoned by being used as a receptacle for offal, the carcasses of diseased animals, etc. During the British occupation many animals perished, and their bodies were dumped into the water regardless of consequences.

"This theory is strengthened by the following facts: (1) The disease first made its appearance in Damietta on June 4th, but was not made public until June 20th, at which time the death-rate became too large for longer concealment. (2) The mortality is confined almost wholly to natives, who disregard in their mode of living all sanitary requirements. (3) The disease is limited to a small territory. (4) Its previous course, on the supposition that it is Asiatic cholera, cannot be traced. (5) The disease does not spread with the rapidity of Asiatic cholera. In 1865 the cholera was only two days in travelling from Damietta to Alexandria.

"I may add that some of the best physicians of Smyrna do not regard the present scourge in Egypt as the cholera. With the stringent measures taken to confine it within its present limits, it is fair to assume that its ravages will not be much further extended, although the death-rates show little diminution as yet."

PRECAUTIONS IN TURKEY.—The International Sanitary Council has imposed twenty-five days quarantine on vessels which have had cases of cholera on board. Other rigid restrictions will also be enforced.

CHOLERA PRECAUTIONS IN AUSTRIA.—The Imperial Board of Health of Lower Austria has issued a series of orders to the health officers of the different Cantons, from which we abstract the following:

1. All sanitaries, cesspools, dungheaps, stables, and other places favorable for the development of disease

germs, and likely to prove nuisances, must be removed, or cleaned and kept in order.

2. On the approach of danger all such places must be disinfected by solutions of sulphate of iron and carbolic acid, at least twice a week.

3. Houses in which cases of cholera or suspicious diseases occur must be disinfected daily.

4. In all buildings in which there are a large number of people, and in houses to which people come and go from different places, as manufactories, police stations, hospitals, railway stations, steamer landings, hotels, restaurants, schools, theatres, etc., must be daily disinfected and subjected to free ventilation.

5. All waters in which suspected patients or persons have washed must be disinfected; and all clothing must be immediately plunged into boiling water or subjected to steam impregnated with 1–50 of carbolic acid; floors and furniture to be cleaned with boiling water containing 1–30 of carbolic acid.

6. In cantons in which an outbreak of cholera occurs all public places are to be closed, and all public meetings are forbidden.

7. All overcrowded rooms, whether used for dwelling or working purposes, are to be partially emptied and ventilated.

8. All suspicious wells and other places from which water is obtained must be closed.

Cholera Hospitals.—Cholera stricken persons, who cannot be properly treated in their own homes shall be carried to a cholera hospital. Proper means for thorough ventilation and disinfectation must be provided and carried out in these hospitals. People dead of cholera shall be buried as quickly as possible in open coffins.—*Medicin.-Chir. Centralbl.*, July 20, 1883.

British Precautions.—The British Government has introduced a bill to centralize hospital management in the event of an outbreak of cholera in London, and it passed first reading in the House of Commons on August 2d.

Sir Charles Dilke, president of the Local Government Board, in presenting the bill, said that the general health of the country was very satisfactory, although there was a large mortality among children in London from diarrhœa. Unusual precaution, he said, would be necessary to guard against cholera until the expiration of six weeks, when, it is believed, the danger will have passed.

Orders have been issued thoroughly to disinfect cargoes of rags arriving at British ports from Egypt.

Precautions in the United States.—The Surgeon General of the Marine-Hospital has received advices that a vessel loaded with rags from Egypt is due at Portland, Me., in a few days. The Acting Secretary of the Treasury has telegraphed the Collector of Customs at Portland not to allow the cargo to be discharged until the local health authorities have inspected it.

Information has been received at Philadelphia that a large cargo of skins and hair had been sent from Cairo and Alexandria on July 9.

Dangerous Wool from Egypt.—The Secretary of the Treasury has received a letter from a prominent firm in New York City, calling attention "to the fact that large quantities of wool of large grade are exported from Egypt, Syria, and countries in their vicinity to this country, which is the principal market for them, besides considerable quantities of 'bed-wools' (extracted from old mattresses) from Constantinople, etc. These wools are frequently transshipped at Marseilles and in England for this country. In view of the terrible epidemic now raging in the Eastern Mediterranean, these wools might convey infection, as well as rags."

Quarantine of Egyptian Rags.—A letter was received by Surgeon-General Hamilton, from the treasurer of the Seymour Paper Company, asking the question: "What is the limit of time when it will be safe to move the (Egyptian) rags to market? He adds that "5000 to 6000 tons of rags are exported annually from Egypt, and nearly all come to the United States. Of course, these rags must be put under the ban, because a small portion, perhaps one ton, is infected. If there is no outlet, they will be saved until the markets are open." Surgeon-General Hamilton suggested that the rags be first dumped into a chlorine vat, at Alexandria, then taken out, dried, and baled, as it would be utterly impossible to fix a time when it would be safe, if ever, to ship rags gathered during an epidemic of cholera.

No more Statistics from Egypt.—The Registrar of the Bureau of Vital Statistics in New York has received an official letter from Amici Bey, Chief of the Sanitary Bureau of Cairo, Egypt, in which he was informed that hereafter no sanitary statistics will be interchanged between that cholera-plagued land and this city. The letter is dated June 21, or some time before cholera had appeared in Cairo. One of the most important duties of the Bureau of Vital Statistics is the compilation of comparative death-records, by which the standing of New York is ascertained among the large cities of the earth. This is done by an exchange of death statistics with other large cities, including Cairo.

The Bey's letter, which is written in French, says that the cessation of all future exchanges is due to the action of the British Government in abolishing the statistical department of the Egyptian sanitary service as a "measure of economy."

Yellow Fever.—The reported escape of two men from the quarantine station at Ship Island last week, has been officially denied by Passed Assistant John Godfrey, U. S. M. H. S., who states the men were not from Ship Island but from Cat Island, and had not been in quarantine. As the crews of all vessels in the various government quaranties and all the employés about the stations are mustered twice daily, desertions would be quickly detected.

The Consul at Vera Cruz has telegraphed the departure of the steamship "City of Puebla" for New York, and the steamer "Statesman" for Brazos, Texas. The Quarantine Commissioner at New York and the Collector of Customs at Brownsville have been informed of the above.

A dispatch was received by the Surgeon-General on the 7th inst. from Dr. Geo. M. Hargis, Sanitary Inspector stationed at Havana, that the steamer "Amethyst" left four cases of yellow fever at that port, and sailed for Boston on the 4th inst.

Up to the present writing there have been no cases of yellow fever, except in quarantine, within the limits of the United States. The latest reports are all favorable to its exclusion from the country this season, and two weeks more of immunity from the disease will render it fairly safe to feel assured that no epidemic of yellow fever is likely to occur. The "danger points"—New Orleans, Pensacola, and the Capes—are very carefully guarded by trusted government officers; the Governor of Louisiana has ordered all infected vessels from the Mississippi Quarantine out of the river and down to the Government Refuge Station at Ship Island; the Pensacola Board of Health permits no infected vessel to remain at the local quarantine station of that port, also sending them to Ship Island; and the pilots at the entrance to Chesapeake Bay are required to convey all vessels from foreign ports to the Cape Charles Quarantine Station at Fisherman's Island, to be inspected before proceeding to their port of destination on the bay—all these precautionary measures, taken with the instructions given to the Sanitary Inspectors of the Marine-Hospital Service stationed at foreign ports to report by cable the departure of vessels from infected localities, whether yellow fever or cholera, would seem to be a sufficient guarantee that nothing has been left undone to prevent the entrance of epidemic disease into the country.

Yellow Fever at Havana.—Forty-nine deaths from yellow fever at Havana were reported last week.

Yellow Fever Quarantine.—The Surgeon-General of the Marine-Hospital Service has been informed that Governor Cameron, of Virginia, has instructed the Virginia pilots to bring infected vessels to anchor opposite the Marine Hospital Quarantine at Cape Charles.

The revenue cutter Forward while on a cruise outside Sand Island, off Mobile Bay, on August 3d, spoke the Norwegian bark Vasco de Gama, from Vera Cruz, with yellow fever on board. The sick were reported to be convalescing, and needing no assistance. The bark was prohibited from coming nearer than ten miles from Mobile bar, and a pilot was not allowed to go on board. The vessel was ordered to Ship Island, and set sail at once.

Sanitary Precautions in District of Columbia.—**Dr. Smith Townshend**, Health Officer of the District, has requested the commissioners to furnish him with $500 to expend in sanitary work about the outskirts of Washington, which are said to be in a deplorably neglected condition. The commissioners have not yet furnished the funds, but have promised him $300 for the purpose.

The Cattle Commission's Report on the Foot and Mouth Disease among American Cattle.—The Treasury Cattle Commission has made the following report to the Treasury Department in regard to the alleged existence of the foot and mouth disease among the cattle in this country:

Charges having been recently made in the British Parliament that cattle were being shipped from our ports infected with the "foot and mouth disease," and a majority of the House of Commons having voted for a resolution opposing the importation into Great Britain of cattle from any country in which said disease exists, we feel it our duty to state the facts of the case, so far as this country is concerned. After a most extended and almost exhaustive inquiry, your Commission have been able to find no trace of "foot and mouth disease," apart from herds just landed from Great Britain, and whole herds have been in every case segregated until the infection has entirely disappeared. The nature and scope of our inquiry may be deduced from our report for 1881. Beginning with the great rendezvous of cattle at Kansas City, Council Bluffs, and Omaha, we have made careful investigations along all the lines of cattle traffic as far as the Eastern seaboard. In this investigation we have included all the great stock-yards where cattle are detained for feeding, watering, sale, etc.; all the great feeding stables connected with distilleries, and starch-glucose, and other factories; all the city diaries where stock-yards exist, and where the herds are replenished from such stock-yards; and to a large extent the great dairymen districts into which cows are drawn from the above-named stock-yards and lines of travel.

Up to the present date we have made observations in the stock-yards at the seaboard, the terminal end of our cattle traffic, and that to which all infection must gravitate, but apart from the imported cases above referred to we have been unable to find a single case of the foot and mouth disease complained of. The significance of the entire absence of this disease along the whole line of our cattle traffic, and in the herds into which this traffic leads, can only be appreciated when considered in its relation to the nature of the disease and the unmistakable symptoms of which it is manifested. The following points are specially to be noted:

First. The foot and mouth disease is perhaps the most contagious malady known. It rarely enters a herd without striking down all the members of that herd simultaneously, or nearly so.

Second. The susceptibility to the disease is all but universal on the part of warm-blooded animals, but all cloven-footed animals are especially and about equally predisposed to it. It cannot be overlooked nor covered up, therefore, as can a disease which confines its ravages to a single genus; but sheep, goats, and swine coming within the range of the infection contract and manifest the disease as readily and in as marked a way as do cattle.

Third. The period of latency or incubation is remarkably short, the eruption of the malady often taking place in thirty-six hours, and rarely being delayed, even in cold weather, beyond six days after exposure to infection. There is, therefore, no opportunity for concealment, nor for the disposal of infected but still apparently sound animals, while a journey of four or six days from the West, with the attendant privations and febrile excitement, would infallibly determine the full eruption of the disease before the stock arrived at the Eastern seaboard, and this although the infection had only been received after shipment on the cars.

Fourth. The manifestation of the disease is not only so universal in the herd affected, but so prominent and unmistakable that it could not possibly be overlooked. No one could ignore for a moment the swollen digits, the lameness, and the blisters or ulcers between the hoofs—the heat, tenderness, swelling, and blisters or raw sores on the udder and teats, and the abundant frothing and slobbering at the mouth, the frequent loud smacking noise made with the tongue and palate, and the large rounded blisters or red angry sores on the mucous membrane of the mouth. These cannot escape the attention of the owners and attendants, and especially when a whole herd of ten, fifty, or one hundred are suffering simultaneously. Much less can they escape the instructed eye of the professional veterinarian.

It may be well to state that the invasion of foot and mouth disease that swept from Canada over Northern New York and New England in 1871 created something closely approaching a panic. The agricultural papers were full of the subject, State boards of agriculture convened and discussed the subject; a convention of delegates from different States met at Albany, N. Y., and it was the engrossing theme for every local farmers' club along the lines of infection. This invasion, imported into Montreal with two English cows, fortunately occurred in autumn, and the long seclusion of the herds during the ensuing winter virtually stamped it out, the infection not having extended beyond herds in inclosed pasturages or buildings. Most of our farmers are as ignorant of the disease to-day of they were in 1871, and any new invasion could not fail to produce a similar excitement and consternation. It should be added that our connection with the States as well as the United States brings us constant complaints of diseases supposed to be contagious, but we have not found any evidence of the actual existence of the foot and mouth disease at any point among our home herds.

We cannot pass unnoticed the two latest importations of the disease from England. Two years ago the steamship France, of the National Line, landed in New York a herd of Channel Island cattle, suffering from foot and mouth disease. These were quarantined by the State authorities and the infection stamped out. The France, however, after an attempted disinfection shipped a cargo of American beeves for the return voyage, and these on arrival in England were condemned as being infected with foot and mouth disease. This was undoubtedly contracted on board ship. The second case is that of the steamship Nessmore, which in March, 1883, landed in Baltimore a herd of Channel Island cattle suffering from foot and mouth disease. These again were secluded as soon as detected by the Pennsylvania authorities, and no evil consequences to our home herds can be traced. But the steamship Nessmore, after an attempted disinfection by the agents, shipped a cargo of American fat cattle, and these on arrival in England were found to be suffering from foot and mouth disease. This infection, unquestionably contracted on board ship, appears to have been the main, if not the sole, occasion of the recent questions and resolution in the British Parliament. That the infection was not derived from American herds, but from English, is beyond all dispute alike in this case and in that of the France, two years ago. The same is true of our extensive invasion in 1871, which was derived from two imported short-horn cows, and which was thoroughly extinguished without having gained any permanent foothold.

We do not deny that other cargoes of American cattle may have been found suffering from the disease in question on arrival in England, but this is amply accounted for by the occasional use for these cattle of herd ropes and other appliances that have been previously used for European cattle. But on this point we insist, with the greatest confidence, that there is no evidence whatever that our American herds are now suffering from foot and mouth disease, and that there is as strong evidence of its non existence as can well be produced on the negative side of a question.

Malaria in Italy.—According to the statistical returns of the Italian Minister of War, more than 40,000 soldiers annually fall victims to malaria in Italy. The cost to the government of maintaining hospitals for patients suffering with malaria is estimated at over $1,400,000. Malarial disease is stated to have increased in extent and virulence since the construction of railways was commenced.

Smallpox in New Orleans.—Smallpox still lingers in New Orleans. For the week ending July 29, the mortality from this disease was twenty-one, or fifteen per cent. of the total mortality.

Dartmouth Medical College.—After forty-seven years of service as Professor of Chemistry in the Dartmouth Medical College, Oliver Payson Hubbard, M.D., LL.D., has resigned his chair and been made Professor Emeritus. Prof. Edwin J. Bartlett, of Dartmouth College, will fill the vacancy during the present lecture term, which opened on August 1st.

A New Medical School in the West.—The Regents of the University of Colorado have recently established a medical department in which the higher standard of medical education will be maintained with a four years' course of nine months each. The school is open free of cost to all qualified persons of either sex and from all parts of the world. The University is located at Boulder, about thirty miles from Denver. All candidates for admission must present a degree in letters or science, or pass an equivalent preliminary examination.

Morphine Mistaken for Quinine.—A few days ago, a resident of Collaton County, S. C., administered to his wife and two children sulphate of morphine, supposing it to be sulphate of quinine. A short time afterward the two children died, and it is feared his wife will not recover.

The American Society of Microscopists held their annual meeting at Chicago, beginning last Tuesday and lasting four days. A large number of papers were read

The Tewksbury Almshouse.—The Massachusetts State Board of Health have appointed Dr. C. J. Fisher Superintendent of the State Almshouse at Tewksbury. A committee was also appointed to visit the almshouse weekly and report to the Board.

Pasteur's Pension.—The Chamber of Deputies passed a law, on July 13th, which gives M. Pasteur an annual life-pension of 25,000 francs, revertible to his wife and children after his death.

Cæsarean Hystero ovariotomy.—Dr. Franzolini has recently performed this operation at Udine. The child was safely delivered. The woman recovered without any serious symptoms.

French Association for the Advancement of Science.—The Administrative Council of this Assotion has decided to establish a Subsection of Hygiene and Public Health, at the meeting in Rouen, on August 16–23, 1883. This subsection is to be ultimately transformed into a section.

Prize Essay on the Experimental Method in Science.—The State Department is informed that the Royal Institute of Higher Studies, at Florence, has offered a prize of 5,000 francs to the person presenting the best essay in Latin or Italian on the experimental method in science. Intending competitors can obtain further particulars by making application to the Chancellor of the Section of Medicine and Surgery of the Institute.

Prof. C. Wedl.—Prof. Wedl has been appointed to the rectorship of the Vienna University for the year 1883–84.

Prof. Winkel.—On account of the removal of Prof. Winkel to Munich, Dr. Leopold will assume the directorship of the Maternity Hospital at Dresden.

New Spirometer.—M. G. Bellangé has recently constructed an apparatus for the measurement of the capacity of the chest, of air expired in a given time, and of the amount of exhaled gases. It consists of a mouth-piece, a spirometer, and a carbonimeter.

Gutter Forceps.—M. Tripier, of Lyon, recently exhibited to the *Société de Chirurgie*, a pair of forceps with open grooves, intended to facilitate the opening of drains and the establishment of counter-openings where necessary.

The Bufalini Prize.—Conforming to the last wishes of the late Prof. Bufalini, the Minister of Public Instruction in Italy has published the conditions of an international competition for the best essay on the *Application of the Experimental Methods to Science*. Manuscripts written in the Italian or Latin language will be received until October, 1884, by the Secretary of the Medical Faculty at Florence. The prize amounts to 5000 francs.

RIBERI PRIZE.—The Riberi prize of 20,000 lire has been awarded to DR. GIULIO BIZZOZERO for his essay on the *Physiopathology of the Blood.*

AMERICAN PUBLIC HEALTH ASSOCIATION.—The American Public Health Association will hold its Eleventh Annual Session at Detroit, Mich., commencing Tuesday, November 13, 1883, and ending Friday, November 16th.

The subjects which have been chosen for special consideration at that time are:

I. *Malaria.* Its etiology and the methods for its prevention in localities or in persons; its American history; its specific particles; its origin; the conditions of its pervasion; its laws of extension, etc.

II. *Foods.* Their adulteration; healthy or deleterious modes of preservation and the function of legislation in regard to them. Ascertained facts as to adulterations in this country. Facts as to canned goods, condensed milk, artificial butter and cheese, prepared meats, etc.

III. *Vital Statistics.* Methods and results; defects apparent. How far foreign modes of tabulation are to be followed. Systems of collection and classification. Race vitality and the care of population as indicated by statistics.

IV. *The Control and Removal of all Decomposable Material from Households.* The mechanical laws, constructions, and appliances relative thereto. The construction of all inside pipes and their connections, their traps and siphonage, flushing, ventilation. How they shall be connected with out-door receptacles, and yet be free from ill effect.

The Executive Committee by this outline desires to avoid general dissertations on these subjects, and to secure facts and opinions as to practical methods of dealing with the interest of public health. Reasons for the views entertained, the results of experience and the best judgment as to preventive and restrictive measures are especially sought.

Methods and systems of physical education, drill, etc., feasible in the school room, will be discussed. While papers of merit on other topics are by no means excluded, it is believed wise to concentrate the preparation of papers and discussion upon these topics.

The Special Committees on Compulsory Vaccination, the Management of Epidemics, and on Diseases of Animals, will, before the completion of their reports, be glad to receive communications from any who have facts or opinions bearing on these subjects.

Gentlemen who propose to present papers are respectfully requested to notify the Secretary by September 1st, and to give the titles of their proposed papers.

The Executive Committee feels warranted in saying that the meeting promises to be one eminently inviting and profitable, and urges the attendance and coöperation of physicians, engineers, architects, teachers, and all those interested in the advancement of public health and physical well-being.

The meeting will be held under the Presidency of Dr. Ezra M. Hunt, of Trenton, N. J.

THE MISSOURI STATE BOARD OF HEALTH was duly organized at Jefferson City, on July 13, by the election of Dr. E. H. Gregory, of St. Louis, as President, and Dr. J. D. Hearn, of Hannibal, as Secretary.

The Board determined to hold an annual meeting in the city of Jefferson on the second Tuesday in January in each year, and regular meetings on the second Tuesday in April, July, and October, at such places as the Board may determine.

According to the rules adopted, the examination of candidates and physicians under the act to regulate the practice of medicine and surgery shall be had at the meeting of the Board in January, April, July, and October, and at no other time, unless ordered by the Board by a vote of two-thirds of all the members.

At a meeting held at St. Louis, on August 1, the Board adopted the Illinois minimum requirement of medical colleges, as follows:

Minimum Requirements for a Medical College to be Held in Good Standing.

First.—Conditions of admission to lecture courses:

1. Creditable certificate of good moral standing.

2. Diplomas of graduation from a good literary and scientific college or high school, or, lacking this,

3. A thorough examination in the branches of a good English education, including mathematics, English composition, and elementary physics or natural philosophy. This provision will not be required before the close of the lecture session of 1883.

Second.—1. Anatomy. 2. Physiology. 3. Chemistry. 4. Materia medica and therapeutics. 5. Theory and practice of medicine. 6. Pathology. 7. Surgery. 8. Obstetrics and gynecology. 9. Hygiene. 10. Medical jurisprudence.

Third.—Length of graduating courses:

1. The time occupied in the regular course or sessions from which students are graduated shall not be less than five months or twenty weeks each.

2. Two full courses of lectures, not within one and the same year of time, shall be required for graduation with the degree of doctor of medicine.

Fourth.—Attendance and examination or quizzes:

1. Regular attendance during the entire lecture courses shall be required, allowance being made only for absences occasioned by the student's sickness, such absences not to exceed twenty per centum of the course.

2. Regular examinations or quizzes to be made by each lecturer or professor daily, or at least twice each week.

3. Final examinations on all branches to be conducted, when practicable, by other competent examiners than the professors in each branch.

Fifth.—Dissections, clinics, and hospital attendances:

1. Each student shall have dissected during two courses.

2. Attendance during at least two terms of clinical and hospital instruction shall be required.

Sixth.—Time of professional studies before graduation shall not be less than three full years, including the time spent with a preceptor, attendance upon lectures, or at clinics and hospital.

Seventh.—Instruction: The college must show that it has a sufficient and competent corps of instructors, and the necessary facilities for teaching, dissections, clinics, etc.

It was resolved that the Secretary of the Board be instructed to prepare a synopsis of the law regulating the practice of medicine and surgery, together with mode of procedure, rulings, interpretations, and decisions on the same on such of them as may be of general interest, and have printed a sufficient number for general distribution.

The Board resolved to coöperate with the Mississippi Valley Sanitary Council.

A circular will be issued by the Board to the effect that it is the opinion of the Attorney-General that all physicians who have not practised five years in this State prior to the passage of the Act and have diplomas shall bring or send them before the Board for examination. All physicians who have no diplomas and were not in practice in this State prior to the passage of the Act shall come before the Board for personal examination and certificate.

The following resolution was adopted:

Resolved, That for the purpose of expediting the business of the Board any one member of the Board can verify a diploma, and such verification accompanying the proper affidavits is sufficient to warrant the Secretary to issue a certificate, *i. e.*, physicians may present their diplomas to any member of the Board, and his verification, with affidavits, will be all that will be necessary for him to apply to the Secretary of the Board of Registration.

The Board issued one hundred and twenty-five certificates for the practice of medicine in the State. Five applicants presented themselves for examination, of whom four were rejected.

The proceedings of the Board are reported to have been quite harmonious, considering the composition of its members, composed as they are of regulars, eclectics, and homœopaths. The examination of applicants for a license has been rigid, as is indicated by the fact that four out of five were rejected, one of the latter being said to be a *protégé* of one of the members of the Board, who is classed as a homœopath.

Dr. Pollak and the Revision of the Code.—At a late meeting of the St. Louis Medical Society, Dr. Pollak, on a question of privilege, read a statement concerning the resolutions offered by him at the meeting of the American Medical Association, from which we make the following extracts:

On Saturday, June 2, 1883, I offered in this Society the following resolution:

Resolved, That the delegates of the St. Louis Medical Society to the meeting of the American Medical Association be requested—not instructed—to move for the appointment of a committee of one member from each State for the purpose of taking into consideration the propriety and advisability of a revision of the Code of Ethics of the American Medical Association, and to report thereon at the meeting of 1884.

This resolution was adopted unanimously. A motion was made and adopted that a preamble be added to the above. And another motion was also passed, that the Revising Committee, if one should be appointed, be authorized to prepare a code, which should be submitted to the American Medical Association in 1884.

In compliance with the resolutions of the St. Louis Society, I prepared a preamble the next day. I read it to Dr. Maughs and to Dr. Jackson, delegates from this city and State, whom I met on the train, for their opinion and frank criticism. Their approval was sufficient to me, and would be so to all unbiased men. They were also shown to the Permanent Secretary of the Association, Dr. Atkinson, and they received his entire assent. He also kindly consented to read them at the meeting. I then offered my preamble and resolutions. If dynamite had exploded in the hall, it could not have caused a greater buzz, stir, and confusion among the 1,500 or 2,000 persons present. A motion to table them was promptly made, and it prevailed by a very large majority. But this was expected, of course, but they were read and understood, and they will have to be put on record.

Up to that time I was utterly unknown, a stranger among strangers. But there was a good deal of handshaking after adjournment by and with hundreds I had not known before. In the nine evening receptions which came off on Thursday, I was met and saluted like an old friend as the champion of reform and of liberal ideas. On that very day, my preamble and resolutions were published *in extenso* in the Cleveland papers, and on the next day the medical and secular papers of the whole United States spread them before the public, suitably commented upon.

On the 9th inst., I made my report to this Society. Dr. Love took exception to it, saying that I had not consulted the St. Louis delegation, which perhaps would have been the proper thing to do; but it had not occurred to me then. I was not required to do it. Besides, we were so scattered in Cleveland that I never met two St. Louisians together at any time until Thursday evening. His main objection was that the preamble did not reflect the spirit of the St. Louis Medical Society, and on the whole they were in bad taste. I maintain that while I may have failed in form, I have certainly strictly obeyed the mandate of the St. Louis Medical Society.

The remainder of the statement was devoted to personal criticism. The Publication Committee declined to insert the paper in the Society's proceedings.

The Pennsylvania Anatomy Act.—By request, we give the text of this act in full, as a model of an efficient law on this subject. The act is entitled "An Act for the promotion of medical science by the distribution and use of unclaimed human bodies for scientific purposes, through a board created for that purpose, and to prevent unauthorized uses and traffic in human bodies."

Section 1. *Be it enacted by the Senate and House of Representatives of the Commonwealth of Pennsylvania in General Assembly met, and it is hereby enacted by the authority of the same*, That the professors of anatomy, the professors of surgery, the demonstrators of anatomy, and the demonstrators of surgery of the medical and dental schools and colleges of this Commonwealth, which are now, or may hereafter become incorporated, together with one representative from each of the unincorporated schools of anatomy or practical surgery within this Commonwealth, in which there are, or, from time to time, at the time of the appointment of such representatives, shall be not less than five scholars, shall be and hereby are constituted a board for the distribution and delivery of dead human bodies hereinafter described, to and among such persons as under the provisions of this act are entitled thereto. The professor of anatomy in the University of Pennsylvania at Philadelphia, shall call a meeting of said board for organization at a time and place to be fixed by him, within thirty days after the passage of this act. The said board shall have full power to establish rules and regulations for its government, and to appoint and remove proper officers, and shall keep full and complete minutes of the transactions, and records shall also be kept under its direction of all bodies received and distributed by said board, and of the persons to whom the same may be distributed, which minutes and records shall be open at all times to the inspection of each member of said board, and of any district attorney of any county within this Commonwealth.

Section 2. All public officers, agents, and servants, and all officers, agents, and servants, of any and every county, city, township, borough, district, and other municipality, and of any and every almshouse, prison, morgue, hospital, or other public institution having charge or control over dead human bodies required to be buried at the public expense, are hereby required to notify the said board of distribution, or such person or persons as may from time to time be designated by said board, or its duly authorized officer or agent, whenever any such body or bodies come to his or their possession, charge, or control; and shall, without fee or reward, deliver such body or bodies, and permit and suffer the said board and its agents, and the physicians and surgeons, from time to time designated by them, who may comply with the provisions of this act, to take and remove all such bodies to be used within this State for the advancement of medical science; but no such notice need be given, nor shall any such body be delivered, if any person claiming to be and satisfying the authorities in charge of said body that he or she is of kindred, or is related by marriage to the deceased, shall claim the said body for burial, but it shall be surrendered for interment; nor shall the notice be given, or body delivered if such deceased person was a traveller who died suddenly, in which case the said body shall be buried.

SECTION 3. The said board or their duly authorized agent may take and receive such bodies so delivered as aforesaid, and shall, upon receiving them, distribute and deliver them to and among the schools, colleges, physicians, and surgeons aforesaid, in manner following: Those bodies needed for lectures and demonstrations by the said schools and colleges incorporated and unincorporated shall first be supplied, the remaining bodies shall then be distributed proportionately and equitably, preference being given to said schools and colleges; the number assigned to each to be based upon the number of students in each dissecting or operative surgery class, which number shall be reported to the board at such times as it may direct. Instead of receiving and delivering said bodies themselves, or through their agents or servants, the board of distribution may, from time to time, either directly or by their authorized officer or agent, designate physicians and surgeons who shall receive them, and the number which each shall receive. Provided always, however, That schools and colleges, incorporated and unincorporated, and physicians or surgeons of the county where the death of the person or such persons described takes place, shall be preferred to all others. And provided also, That for this purpose such dead body shall be held subject to their order in the county where the death occurs for a period not less than twenty-four hours.

SECTION 4. The said board may employ a carrier or carriers for the conveyance of said bodies, which shall be well enclosed within a suitable encasement, and carefully deposited free from public observation. Said carrier shall obtain receipts by name, or, if the person be unknown, by a description for each body delivered by him, and shall deposit said receipt with the secretary of the said board.

SECTION 5. No school, college, physician, or surgeon, shall be allowed or permitted to receive any such body or bodies until a bond shall have been given to the Commonwealth by such physician or surgeon, or by, or in behalf of such school or college, to be approved by the Prothonotary of the Court of Common Pleas in and for the county in which such physician or surgeon shall reside, or in which such school or college may be situate, and to be filed in the office of said Prothonotary, which bond shall be in the penal sum of one thousand dollars, conditioned that all such bodies which the said physician or surgeon, or the said school or college, shall receive thereafter, shall be used only for the promotion of medical science within this State; and whosoever shall sell or buy such body or bodies, or in any way traffic in the same, or shall transmit or convey, or cause to procure to be transmitted or conveyed, said body or bodies to any place outside of this State, shall be deemed guilty of a misdemeanor, and shall, on conviction, be liable to a fine not exceeding two hundred dollars, or be imprisoned for a term not exceeding one year.

SECTION 6. Neither the Commonwealth, nor any county or municipality, nor any officer, agent, or servant thereof, shall be at any expense by reason of the delivery or distribution of any such body, but all the expenses thereof, and of said board of distribution, shall be paid by those receiving the bodies, in such manner as may be specified by said board of distribution, or otherwise agreed upon.

SECTION 7. That any person having duties enjoined upon him by the provision of this act, who shall neglect, refuse, or omit to perform the same as hereby required shall, on conviction thereof, be liable to fine of not less than one hundred nor more than five hundred dollars for each offence.

SECTION 8. That all acts or parts of acts inconsistent with this act be and the same are hereby repealed.

DA COSTA'S DIAGNOSIS.—We learn that the first edition of the German translation of this justly popular work has been exhausted in less than nine months after its publication. That a translation of a foreign book should attain such remarkable popularity, within such a short space of time, is a high tribute to its merits.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending July 28, 1883, indicate that cholera morbus, consumption, and dysentery have increased, that diarrhœa has considerably decreased, and that measles, pneumonia, and cerebro-spinal meningitis have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending July 28, and since, at twelve places; scarlet fever at fourteen places; and measles at ten places.

OBITUARY RECORD.—DR. DUBROVO, editor of the *Annals* of the Moscow Chirurgical Society, has recently died of diphtheria, contracted from a patient upon whom he had performed tracheotomy.

NOTES AND QUERIES.

HYSTERO-EPILEPSY.

To the Editor of THE MEDICAL NEWS.

SIR: There is an article in your journal of July 28, 1883, by Dr. E. J. Kempf, of Ferdinand, Indiana, relating to a case of hystero-epilepsy in a boy.

As it is well known to the profession that many cases of hysteria and epilepsy are induced, both in the male and female, by habits of masturbation, might not this one proceed, in a measure, from the same cause? His habits and disposition, in my humble opinion, seem to favor such an idea.

I am yours obediently,

JOHN C. WHITE, L R.C P. Edin., etc.

NEW YORK, July 30, 1883.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 30 TO AUGUST 6, 1883.

MAGRUDER, DAVID L., *Lieutenant-Colonel and Surgeon.*—The leave of absence extended one month.—*S. O. 89, Military Division of the Missouri, August* 4, 1883.

FORWOOD, WILLIAM H., *Major and Surgeon.*—To proceed to Fort Washakie, Wyoming, and Fort Ellis, Montana, on public business and return.—*S. O. 87., Military Division of the Missouri, August* 2, 1883.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

VESICO-VAGINAL AND RECTO-VAGINAL FISTULA.

A Clinical Lecture, delivered at the Jefferson Medical College Hospital.

BY J. EWING MEARS, M.D.,
GYNECOLOGIST TO THE HOSPITAL.

GENTLEMEN: You will remember the patient now before you as the one presented some three weeks since suffering from a vesico-vaginal fistula. At that time, I made an examination of the opening, and described to you its size and position, being as large as a quarter of a dollar piece, and situated high up near the mouth of the uterus. You will recall that I spoke of the tense and thickened condition of the vesico-vaginal wall, and stated that it was a condition due to the opening in the bladder which had existed for so long a period. I alluded to the methods of treatment by the denudation of the edges and the introduction of sutures employed in these cases, and called attention to the fact that, in many cases, repeated operations were required to secure entire closure of the fistulous opening.

Since the patient visited the clinic, I have operated upon her, and I am gratified in being able to report that I have succeeded in closing the opening at one operation. Many difficulties were encountered, however, in obtaining this favorable result, and of these I shall speak now. In the first place, the day chosen for the operation was very unfavorable, so far as the proper light was concerned—"cloudy with partially clearing weather," as the Signal Bureau would state it, this condition affording a very uncertain light—one moment dark, and another fairly light, with varying changes from one to the other; not only uncertain was the light, but it was decidedly annoying. So many difficulties did this bad light introduce that a friend who happened into the operating-room strongly advised me to abandon the attempt at closure at that time. The patient, however, was so anxious to have the operation performed, and as I had been compelled, for other reasons, to disappoint her on one or two occasions, I decided to persevere and complete it. Under ordinary circumstances, I should adhere to the very good rule of selecting, as a day for an operation of this character, one in which the light was the best, and I should delay the operation if such was not the case.

The high position of the opening presented some difficulties which were increased by the absence of a good light. You can readily understand how much more difficult the manipulations would be which are required in using instruments in an operation upon a point high up in a tube, like the vagina, than those necessary at the orifice. Moreover, the canal was much contracted, and, for this reason, the opening could not be readily exposed.

I have referred to the tense condition of the anterior vaginal wall the result of the permanent opening in the vesical wall. This condition prevented the approximation of the edges of the opening without undue tension. In order to overcome this I made "relaxing" incisions, as they may be termed, through the mucous membrane, and after breaking up the connecting vesico-vaginal fascia slid the membrane up and in this manner relieved the tension. I was careful in denuding the borders of the opening to secure an ample raw surface completely encircling it, so that the surfaces apposed after the introduction of the suture would be denuded. This is of the utmost importance in order to obtain complete union. Before introducing the sutures the edges should be brought together, and a careful examination made with regard to this point.

For the purpose of introducing the sutures I employed, as is my custom, a long-handled needle slightly curved with an eye in the point. This needle I introduced about the one-sixth of an inch outside of the margin of the denuded surface, passed it beneath the tissues through the edge of the opening, carried it across the opening into the opposite edge at a corresponding position, and in the same way brought it out at a point opposite to that of entrance. It is necessary to steady the tissues with a tenaculum, and a blunt-pointed hook will assist in the passage of the needle if placed behind its point as it emerges. The needle being held in position is armed with silver wire and withdrawn, in this manner depositing the suture without difficulty. This method of introducing the sutures in these operations I regard as possessing advantages over that of using the small vesico-vaginal needles. These needles, besides being difficult to introduce, are liable to break and thus complicate the operation. In the efforts made at introduction lacerations of the tissue also frequently occur. In this case four silver-wire sutures were introduced and clamped with perforated shot. The sutures were removed on the tenth day. A metal self-retaining catheter was kept in the bladder for a period of twelve days. On removal of the catheter the patient was able to empty the bladder, the urethra being used for that purpose the first time in thirty-seven years. At the end of the second week the patient was permitted to get out of bed, and the bowels were relieved by an enema.

The gratification which the patient expresses at the favorable result following the operation is quite manifest. She describes, in a graphic manner, the sufferings she has endured in the past thirty-seven years—"scalded in the summer" and "frozen in the winter" by the constant flow of urine. Each night she retired with a basket of dry cloths beside her bed, and during the night she was kept busy in removing the wet and readjusting the dry. Now, she passes water but four times in the twenty-four hours, and enjoys a relief from suffering, the extent of which she can scarcely appreciate.

I also present to-day three patients who have suffered with recto-labial and recto-vaginal fistulæ. These lesions are caused by prolonged pressure of the child's head in parturition, direct injury, as may occur in the use of the forceps during delivery, and ulceration or abscess. Prolonged pressure and direct injury by instruments are more liable to produce vesico-vaginal fistulæ, whilst ulceration is the most prolific cause of the recto-vaginal variety. Stricture of the rectum, due either to malignant or syphilitic disease, is very frequently the exciting cause of the ulceration, and should always be considered in connection with the adoption of any surgical procedures.

Inflammation occurring between the vagina and rectum, involving the recto-vaginal fascia, may eventuate in abscess, which may open into both cavities, or the pus may gravitate towards the perineum, and escape into the rectum, just behind the sphincter ani, and also burrow through one labium, forming a fistulous tract connecting the rectum and labium.

The symptoms presented in all of the varieties of these fistulæ are the escape of gas or fecal matter into the vagina, or through the fistulous tract into the labium. When the opening is large, the discomfort is very great, the patient having very imperfect or no control over the movement of the bowels. In simple cases, not associated with stricture or disease of the rectum, the methods of treatment are similar to those used in cases of anal fistulæ—cauterization by mineral acids and the actual cautery; nitrate of silver, either in solution or solid form, and tincture of iodine are recommended.

In larger openings between the rectum and vagina, closure may be effected by means of sutures, as in the vesico-vaginal variety, or when situated near the sphincter ani, this muscle, with the recto-vaginal wall, may be divided by the knife, or cut through with the ligature. In the case of recto-labial fistula now before us, I performed two operations—the first with only partial success. In the first operation, I employed a method described as that of the late Dr. John Rhea Barton, of this city, which consisted in the complete division of the sphincter ani laterally, and on the side of the labial opening, in this instance, as it usually happens, on the left side. The finger was introduced into the bowel, the curved bistoury carried along it and the muscle divided by cutting from within outwards. The principle of the operation you can understand, the object being to secure complete relaxation of the parts, thus permitting the walls of the fistulous tract to come in contact, and union to occur as a result. In this case, I had only partial success, owing, it may be, to a failure to divide all of the fibres of the sphincter; complete division is essential to success, and care should be taken to accomplish it. The second operation consisted in division of the wall of the fistula on the grooved director, as is practised in anal fistulæ, the parts healing by granulation.

In the two cases of recto-vaginal fistulæ, I closed one by suture after denuding the margins freely without dividing the sphincter ani. This opening was quite small, and the vaginal wall was so relaxed that no tension was exerted by the sphincter. In the other case, the opening was large enough to admit the end of the index finger, and was situated just behind the sphincter muscle. On division of the remaining portion of the perineum, it was found to contain a fistulous tract in which feces were lodged. The parts were freely cut away, so as to remove entirely the fistulous canal; the edges and borders of the opening denuded for some distance up into the vaginal tube, and the mucous membrane dissected from the inner surface of the labia, as is done in cases of perineorrhaphy, where the bowel is involved.

Silver-wire sutures, vaginal, superficial, and deep perineal—in all, fourteen—were used to approximate the parts. The quilled suture was used in bringing together the deeper surfaces of the perineum. Complete union followed in this case.

The superficial perineal sutures were removed on the sixth, the deep on the eighth, and the vaginal on the tenth day. The patient was kept on the back or side, with the limbs fastened together, for three weeks, and the bowels were opened by a large dose of oil, aided by enemata, on the nineteenth day.

In the treatment of these varieties of fistulæ, success depends in great measure, as in the vesico-vaginal forms, upon careful preliminary preparation, and, after operation, care. Where the opening is due to syphilitic disease, specific remedies should be given for some time preceding any surgical procedures.

A REPORT OF A VERY LARGE SOLID FIBRO-CYSTOMA OF THE OVARY.

OPERATION FOR ITS REMOVAL; FATAL RESULT; WITH REMARKS.

BY WALTER IZARD, M.D.,
OF LYNCHBURG, VA.

My object in reporting the following case is not so much to show anything especially unique, either in the tumor or the operation, although the great size and peculiar structure of the former would entitle it to special interest, as to attract attention to the difficulty which exists in some conditions in making a correct diagnosis as to structure, before operating, without resorting to the expedient of aspiration or tapping as a diagnostic measure.

April 15, 1881.—M. C., colored, æt. 40 (about), called on me for the purpose of having a large abdominal tumor removed. In appearance she was decidedly larger than a woman at the full term of utero-gestation; general health fairly good, although she was losing flesh rapidly according to her own statement. She said the tumor had first began to attract her attention about three years previously, as a very slight enlargement in the right inguino-iliac region, that its growth had been very slow until the past ten months, since which time it had been rapid—nearly all of its present enormous size had been gained within that time; the tumor had never been painful until lately, when she had suffered much from the effects of its weight, having constant backache, sharp pains in thighs and abdomen, great irritability of the bladder, hemorrhoids, alternate diarrhœa and constipation, etc. The menstrual function was still active, regular and normal in quantity and duration. Of late she had suffered much from œdema of the lower extremities, locomotion had gotten to be difficult and laborious, and she was incapacitated by her size and sufferings from pursuing her daily avocation, upon which she was dependent for a living. She urgently requested its removal.

Physical Examination.—The abdomen, upon inspection was ovoid in shape; upon palpation the tumor appeared to fill the entire abdominal cavity, its fundus reaching to the ensiform cartilage and encroaching upon the diaphragm to the embarrassment of respiration; it communicated a highly elastic sensation to the touch; *fluctuation was distinct* and unmistakable; careful percussion and auscultation confirmed the above indications of its size and character. The uterus, upon examination, was *in situ* and healthy, the sound introduced showed the extent of its cavity to be three inches (she had borne children).

Dr. John W. Sale, of Liberty, Va., then my partner in the practice of medicine, was called in consultation and agreed with me in the diagnosis, which was cystic tumor of the right ovary. Thinking the case a favorable one and conceiving that nothing was to be gained by delay, I agreed to remove the tumor, and a day in the following week was fixed for the operation; in the mean time the patient was put upon the preparatory treatment usual in cases for ovariotomy, and all the arrangements as to cleanliness and general hygiene about the room to be occupied by the patient were strictly attended to. A second examination previous to the time set for the operation confirmed my opinion on all points.

April 25th, at 12 M., I proceeded to operate in the presence of and assisted by Dr. John W. Sale, Dr. E. W. Sale, Dr. J. C. Brown, and Dr. F. Sale, then a medical student. The usual incision about three inches in length was made between the umbilicus and pubis in the median line; upon opening the peritoneum a considerable quantity of straw-colored serum escaped and the tumor appeared in the incision red and fleshy in appearance and very firm and elastic in feel. The trocar plunged into it in two places obtained nothing but a few drops of venous blood; there was of course no diminution in its size; the incision was then prolonged upwards by the side of the umbilicus and the hand was introduced to examine its attachments; it was found to be free from adhesions anteriorly, but posteriorly it was closely adherent throughout the whole of its extent, the adhesions involved the sheath of the aorta, the common internal and external iliacs, the vertebral column, and the whole posterior aspect of the abdominal cavity; there were no adhesions to the bladder or uterus; it arose from a very stout, fleshy pedicle on the right side in the region of the ovary. The tumor was then with caution and great difficulty peeled off from all its attachments and turned out of its bed; this was accomplished without injury to any of the important vessels with which it was in relation. Two of the gentlemen assisting me then held it up, with difficulty, on account of its size and weight, while I transfixed the pedicle and tied it in two parts with a ligature prepared of twisted saddler's silk; the tumor was then cut off. The pedicle, which was very short, was about two inches in diameter, and was found to consist of a perfect mass of bloodvessels simply bound together by connective tissue of a fibrous character. The arteries varied in calibre from the size of the brachial artery to that of the most minute arteriole. Owing to the dense and unyielding character of the pedicle the stout double ligatures thrown around it were found totally inefficient to control the hemorrhage from these numerous vessels. Other expedients were tried, but the same cause prevented any means of compression in mass or in subdivision from succeeding, so that it became necessary to secure each vessel separately, which was done; most of them were ligated, while torsion was practised with a few. Very little blood was lost, comparatively, during the operation, the gentlemen assisting me rendering valuable aid in compressing the pedicle during the ligation of the vessels. The peritoneal cavity was then carefully sponged out, and the wound, which it had been found necessary to enlarge so that it finally extended nearly from the ensiform cartilage to the pubis, was closed with silver wire sutures including the peritoneum, alternated with silk sutures involving only the skin and cellular tissue; the pedicle, with its bunch of ligatures, was secured in the inferior angle of the wound. The patient, whose pulse had continued good throughout the operation and whose surface was pleasantly warm, was then put to bed, warmly covered, and surrounded with bottles containing hot water. She rallied promptly from the chloroform and expressed herself as feeling moderately comfortable, though she complained constantly of thirst. The operation occupied about an hour and a half.

The Tumor.—Weight forty pounds. Upon section was found to consist of layers and bundles of fibres eccentrically arranged, running in different directions, but at somewhat regular intervals gathering themselves into a concentric shape, and running round a small cyst. These cysts, dispersed with considerable regularity throughout the tumor, varied from the size of a walnut to that of a small bullet, and uniformly contained a homogeneous gelatinoid substance; the portion of the tumor immediately surrounding these cysts, occupied by the concentric laminæ, was pale and poorly supplied with blood, while the remainder of the tumor was enriched by a most abundant circulation.

Just at the point of entrance of the pedicle into the tumor, a smaller tumor, about the size of a large orange, was attached to the larger one by a short and fleshy pedicle.

The patient died during the ensuing night from shock. The apparent rally after the operation was not maintained—thirst increased, jactitation came on, succeeded by symptoms of exhaustion, and these were rapidly followed by collapse and death; a result to be expected from the character of the tumor and the enormous amount of pressure that was suddenly removed from the vessels and nerves of the abdominal region, besides the large amount of blood which was actually removed from the circulation in the removal of the tumor.

Remarks.—It is, perhaps, needless for me to say that if the nature of this tumor had been made out before operating, the operation would not have been performed. The object of this paper is to call attention by adding this to the record of similar cases heretofore operated on by others under similar misapprehension, to the fact that the mistake made in this case is one easily made under similar circumstances, not only by the inexperienced, but by those who are careful to use all the means in their power to clear all points of doubt before resorting to so grave an operation, as even a favorable ovariotomy would be. In this case the tumor filling the abdominal cavity, and giving to the external appearance its oval form, was uniformly covered to the depth of about half an inch with the serous fluid effused in the peritoneum as a result of pressure—this fluid communicated the sense of fluctuation in examining the tumor, and alteration of the position of the patient produced no gravitation of the fluid to dependent parts, because of the complete filling of the abdominal cavity with tumor and exudation. The patient was not tapped or aspirated, a measure that would have pointed out the true nature of the tumor, in obedience to the opinion held generally, I believe, by ovariotomists, that this measure is not advisable in cases where an operation is contemplated, and where the other signs of an ovarian cyst are sufficiently clear as to leave no reasonable doubt as to the nature of the tumor. I think it will be agreed that this was the case in this instance.

Emmet, in his *Practice of Gynæcology*, records a case of a woman applying at the Woman's Hospital, New York, with a tumor for removal, which he at first suspected to be a uterine fibroid, but the woman being seen and examined subsequently by Drs. Sims, Thomas,.and Peaslee, and they holding the opinion that it was an ovarian cyst, he became convinced that they were right, operated for its removal and found it a uterine fibroid. The patient died from shock in a few hours. I cannot cite the page where the account of this case can be found, as I have not the book by me, but it is in his article on "Ovariotomy" in the edition of 1878 or 1879 of his valuable work on Gynæcology.

In the AMERICAN JOURNAL OF THE MEDICAL SCIENCES for October, 1871, page 433, Dr. Packard reports to the College of Physicians of Philadelphia, a case diagnosticated as ovarian cyst by himself and others, in which he proceeded to operate for the removal of the tumor; but, having introduced the trocar into the uterus, under the impression that it was one of the cysts, and having therefrom some troublesome hemorrhage, he secured the bleeding points, and then, considering the removal of the tumor impracticable, he desisted from the operation, and closed the wounds, uterine and abdominal. The patient, however, had symptoms of peritonitis and metritis, and died on the 14th day after the operation. An autopsy was made, and he says of the tumor that it "was fibrous and solid, and presented a most deceptive fluctuation; it seemed to have been developed from several centres, chiefly, perhaps, from the left ovary; a strong fibrous pedicle connected it with the upper and back part of the uterus. In the centre of one fibrous mass was what seemed to be a shrunken cyst. The whole tumor was judged to weigh thirteen or fourteen pounds," etc.

In THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES for July, 1871, page 157, Dr. Walter F. Atlee reports to the College of Physicians of Philadelphia an operation performed by him on a woman fifty-two years old for the removal of a tumor about the size of the adult head, under the belief that it was a cyst of the right ovary. The tumor proved to be a uterine myoma, which nearly obliterated the cavity of the uterus; it weighed five pounds. This operation was really one of extirpation of the uterus. The patient recovered without a bad symptom.

I have within my own experience known two other cases, which I can only refer to, as they have never been published. One was in a western city, and multiple subperitoneal uterine fibroids were removed from a lady, under the impression that the tumor was a multilocular ovarian cyst, resulting in death from shock in a few hours. The operator was a distinguished ovariotomist from one of the large eastern cities, who went west for the purpose of operating. The other case occurred in one of the counties adjacent to this city, and was operated on by a surgeon of the section where the lady lived. This was also a fibroma of the uterus, and death resulted within forty-eight hours; cause unknown.

I do not wish to be understood as attempting to give the complete bibliography of what may be termed these mistaken operations. Suffice it to say that, since this operation, I have found record or reference to about a hundred of these operations under mistaken diagnosis. My object is simply to add to the clinical record of them, and also by means of such addition to set forth the need of the greatest caution in diagnosis. Tapping, when it is performed, ought to make the case clear, but even this sometimes fails, as it was performed in Dr. Packard's case without a diagnosis of fibroid being made.

My own case has some points of peculiarity as compared with the others. It was the only one, except Dr. Packard's, in which the tumor arose from the ovary, all the others being fibroids of the uterus; also it was the largest that has come within my observation or reading, and, lastly, its structure was, I believe, a very unusual form of ovarian disease. I regret that I cannot add a report of a microscopic examination of its minute structure, but none was made.

REMARKS ON SOME OF THE RELATIONS WHICH ANIMAL HEAT AND NERVE FORCE OR MOTION BEAR TO EACH OTHER.

BY ROBERT BIRD, M.D.,
OF COBHAM, VA.

HEAT and nerve force—are these mutually convertible? Light, when it impinges on the retinæ, becomes physiological force;[1] sound may, when it falls on the auditory nerve, induce neuralgia—that is, physiological changed into pathological motion;[2] while words conceived in the brain may become physiological motion in the mouth and hollows of the throat, physical force in the atmosphere, and again physiological motion in the auditory nerve and the brain, as happens when we select and speak words to produce an echo.[2] This being the case, it is not unreasonable to suspect that heat may, under certain circumstances and conditions, become directly transformed into nerve force or motion, and, *vice versa*, that nerve force may be transformed into heat. By directly transformed is meant that the one is changed into the other directly as heat is changed into electricity in the thermo-electric pile, and not through a chemical or any other medium.

In the processes which constitute artificial egg-hatching, we have, at the touch of heat, an instance of development of lowly organized matter into an animal in which the higher displays of life are manifested. It has not yet been experimentally demonstrated that in these processes heat is directly transformed into nerve force or motion, but that it is so appears to be assumed by at least one of our leading physiologists.[1] When this reasonable assumption has been strictly verified, it will then clearly appear that nerve force takes its place in the circle of the forces, and does its share of work in the general round. The warmth of the egg-hatcher leads to the hatching out of fully developed chickens, which are capable of doing all that chickens hatched in the ordinary way are capable of doing. They eat and grow, move about, and deal as intelligently with their surroundings as chickens usually do, and in time they may produce eggs, and hatch them in the natural manner. Here we have artificial heat, nerve force, animal heat, and nerve force following each other in orderly succession, the result of which, as these operate on organic matter, is a complex physiological display, constituting a fowl and its life. In the course of this physiological development, we see, on the one hand, that the cell or egg has certain tendencies and capacities which compel and enable it to develop in certain directions, within certain limits, and after certain patterns, and, on the other hand, we see the numberless and far-reaching operations of the nervous force ministering to the growth, the maintenance, and general well-being of the body. Heat in these processes can scarcely take the place of these tendencies and capacities, but it may reasonably be concluded that it is, in some way, and to some extent, changed into the nerve force, which, as it were, carries out their mandates.

---

[1] See the author's paper in Indian Medical Gazette, Calcutta, November, 1880, "On the Retinal Spectra."

[2] On Sound as a Cause of Disease, *Idem*, April, 1874.

Chossat,[2] in the course of his experimental researches into the effects of starvation on animals, found that these continued to lose in temperature as the starvation was continued, and that when the loss had reached a certain limit (varying in the individuals experimented on), the animals suddenly died. But he also found that, when this limit was nearly reached, and the animals about to die, if he applied external warmth the dying creatures at once began to recover the use of their senses and their muscles, and took food when it was offered to them. Further, if the application of artificial warmth was continued long enough, they digested the food, gained in temperature and strength, and soon again became independent animals; but if it was withdrawn too soon, they relapsed and died. The restoration to life in these experiments which followed the application of heat was, I think, too sudden and quick to admit of any other conclusion than this, viz., that the heat became directly transformed into nerve force in the nerves and nerve centres, which, permeating the dying tissues, maintained vitality till the restored sustenance had been digested and assimilated.

John Hunter[3] instituted some experiments to test the power of living bodies to resist the effects of heat and cold. In one of these he immersed a dead and a living penis in warm water, and carefully measured the rise of temperature in each. He says "the living and dead parts, being both immersed in water gradually made warmer from 100° to 118°, and continued in that heat for some minutes, the dead part raised the thermometer to 114°, while the living raised it no higher than 102½°. It was observed by the person on whom the experiment was made that after the parts had been in the water about a minute, the water did not feel hot; but on its being agitated it felt so hot that he could hardly bear it. Upon applying the thermometer to the sides of the living glans the quicksilver immediately fell from 118° to about 104°, while it did not fall more than a degree when put close to the dead; so that the living glans cooled the surrounding water to a certain distance."

At first it appears as though the dead penis had taken in more heat than the living penis, but that this is only in appearance is indicated by the living glans cooling the surrounding medium from 118° down to 104°, so that this (the living glans) not only absorbed the 14° missing from the water in contact with it, but its own special share of heat also. What did it do with the missing heat? That is the 14° added to the 11½° which marked the difference between the temperatures of the dead and living parts. That it absorbed them is certain, but that it did not continue to retain them in the form of heat is equally certain, as the applied thermometer only registered a temperature of 102½°, while the surrounding medium stood at 118°. Nor can it be concluded that it conveyed them away by conduction, for heat travels much too slowly among the living tissues by conduction to admit of the phenomenon being explained in this way. By a process of elimination we are almost driven to conclude that the missing heat, having been transformed into nerve force, was, in this form, transferred to the nerve centres. The above simple experiment, made by so exact and eminent a man as John Hunter was, will bear a good deal of thinking over. In explaining the restorative effects of heat on animals rendered insensible by exposure to cold, or the increase in the mortality, which invariably occurs among the very young and very old, when the weather suddenly becomes very hot or very cold, a chemist would use the principles of chemistry, and a physicist the principles of physics, while a physiologist, if he would arrive at the truth, must use all the principles, whether these are mechanical, chemical, or physical; and when, on the one hand, he teaches that the force which fills the brain and other ganglia is mainly produced chemically through the oxidization of the nerve substance, he may, on the other, admit that in some instances and to some extent it is derived directly from heat, and that in others it is reconverted into heat, and as such radiated into the colder space of the surrounding atmosphere. The capacity of the nervous system, however, is limited in dealing with heat impinging on it. When acted on by more than it can dispose of, then death results—the death of a part if the application be local, or death of the whole body if the application be general, as instanced by burns and scalds ensuing on contact with hot water and hot metals, and by the occurrence of *coup de soleil* and heat apoplexy—the result of exposure to the sun's rays in tropical climates.

[3] Palmer's edition of his works, vol. iv. pp. 140, 141.

"When the doctrine now known as that of the conservation of energy was first worked out in regard to the production of animal force, it was supposed that every exertion of muscular power involved a metamorphosis of the tissue of the muscle itself sufficient in its amount to produce the mechanical equivalent of the heat that would be otherwise liberated by the combustion of its hydrocarbon. But the observations of MM. Fick and Visliscenus on the increase of urea and other nitrogenous products of the disintegration of the muscles which shows itself in the urine during and after prolonged muscular exertion, confirmed, as they have been, by the results of many similar inquiries, seem to place it beyond doubt that the amount of motor energy put forth is so completely out of proportion to that of the muscular tissue, which we can suppose to have been consumed, that we cannot do otherwise than attribute it in great part to the oxygenation of the non-azotized components of the blood during its passage through the muscle."[1] As the question is still an open one, the discrepancy above alluded to might also be explained by affirming that, in muscular contraction, the nerve force poured upon the muscles is transformed into motion, as heat or electricity is in moving machinery, and that the excreted urea is merely a measure of the waste of the muscle doing the work, and not of the force by which the work is done. This statement is supported by many other phenomena, and scarcely contradicted by any. During and after the convulsions of epilepsy, and the exacerbations of the spasms in tetanus, the temperature of the body rises. In epilepsy, I have seen the temperature rise from 99° to 104°, and in tetanus it has been noted as high as 110°.[2] To all appearances, there is in these diseases a sudden and violent overflow of nerve force from the centres upon the muscles—an overflow which is too excessive to be wholly used up in the ordinary way. The muscles convert the larger proportion into violent motion, while the remainder is converted into heat through resistance, just as electricity is converted into heat in its passage through platinum. It does not ever appear that muscles are capable of contracting without the application of some stimulus, while it does appear that the ability of the muscle to contract at all depends on its tissues being maintained in a certain condition. But in debating this question, it is necessary to separate the instrument and the force which moves it. Brown-Séquard's experiments[3] show how essentially necessary a sufficient supply of arterial blood is to the maintenance of contractility, but they do not indicate that the blood furnishes the motive power. Nerve force is the natural motive power of muscle, but some other forces may be substituted for this in producing muscular contraction, as, for instance, physical contact. It must, however, be noted that these forces, or stimuli, come from outside the muscle, and are not inherent in it or a property of it.

Pathology in many of its phases supports the statement that nerve force is directly convertible into heat. The rise of temperature in ague does so. In the beginning of this disease the patient complains of feeling very cold, and shivers. Yet simultaneously with the coming on of the shivering the temperature of the skin begins to rise, and in the course of a few minutes, and while the patient is still shivering, the skin has grown burning hot. It appears to be almost necessary in this instance, in the absence of any other satisfactory explanation, to attribute the sudden rise in temperature to a sudden metastasis of nerve motion from the centres upon the periphery. For it can scarcely be attributed to an increased flow of blood through the capillaries, and to an increase in the disintegration or oxidization of the tissues consequent on this; because there is no such increase in the blood flow, as is proved by the skin remaining blue and pinched, and that there is as yet no increase in the generation of carbonic acid in the tissues seems also to be proved by the labors of Lehmann,[1] which go to show that the amount of carbonic acid from the body is lessened and not increased in intermittent and other fevers. The trembling or irregular action of the muscles also indicates that a metastasis or overflow of the nerve force is in progress. Through what channels does the force or motion flow? Probably along or through both the afferent and efferent nerves, for the paradoxical experiment shows that the same nerve motion may travel along both.[2]

In proving that the generation of animal heat is at any rate not altogether dependent on the oxidization of carbon during respiration, or necessarily on oxidization of carbon at all, Sir Benjamin Brodie adduces the following cases: "A man met with an accident which occasioned a forcible separation of the fifth and sixth vertebræ of the neck attended with an effusion of blood within the theca vertebralis and a laceration of the lower part ot the cervical portion of the spinal cord . . . the patient in this instance died at the end of twenty-two hours from the period of the injury, and for a considerable time previously to his death, breathed at very long intervals, the pulse being weak and the countenance livid. At last there were not more than five or six inspirations in a minute. Nevertheless, when the ball of a small thermometer was placed in the inside of the groin the quicksilver rose to 111° of F. Immediately after death the temperature was examined in the same situation and found to be still the same."[3] Is it unreasonable to conclude that in this and similar cases the heat was generated by an excessive flow of nerve motion towards the periphery and the direct conversion, through resistance, of this into heat on the skin and outer tissues of the man. That this idea had at least partly formed itself in the mind of Brodie is evident from his further remark, "there seems to be no reason why the evolution of heat should not be one of the results of the operation of the nervous power as it is of electricity."[1]

[2] Paradoxical contraction of muscle.

[3] Physiological Researches, pp. 120–121; and for a somewhat similar case see *Lancet* (London), March 6, 1875, detailed by Dr. Teale.

Dr. Dowler, of New Orleans, observed that the temperature of the bodies of those who had died from yellow fever often rose to a remarkable height immediately or shortly after death. In one instance just before death the temperature was 104° and fifteen minutes after death it had risen to 113° in an incision of the thigh.[2] It is very noteworthy that Dr. Dowler almost invariably found that the lowest temperature was to be met with in the brain. A corresponding rise of temperature is often observed in the bodies of those who have died from Asiatic cholera. In this disease, as is well known, one of the leading symptoms is great depression of temperature. It is not unusual to see this fall, as the disease progresses, from the normal standard to 85°, 80°, and even lower in the cold season, while after death it will often rise to 100°, 102°, or 104°. Now how are these post-mortem rises in the temperature to be explained? They cannot result from the oxidization of carbon during respiration, for respiration has ceased, nor from the processes of secretion, assimilation, or nutrition, for these also have ceased, nor from muscular contraction, for the rise is often an accomplished fact, before the slightest trace of rigor mortis is apparent. But can these processes, when in full operation combined with muscular contraction, and with the heat of fever thrown in to help, can they generate so high a temperature as 113°? The vital or physiological processes generate a temperature of from 98.5° to 101° according to the locality examined, while combined with fever they rarely, if ever, produce a temperature of more than 108° or 109°, but in Dr. Dowler's cases the post-mortem temperature exceeded the fever-heat, and in one instance when the fever-heat rose to only 104° the post-mortem temperature rose to 113°. I think we must attribute this remarkable rise to some other source than the after-death contraction of muscle. Can it reasonably be attributed as has been done in other cases—in cases of tetanus and injury to the spinal chord—to a metastatic flow of the nerve force? Water, when freezing gives out heat; is it permissible to say that the nerve centres when dying give out their special motion in copious flow along the nerves, and that, as this cannot now be utilized in carrying on the processes of life, it is necessarily converted into heat by collision with the dead tissues? In cases of death, after lingering illness, attended with much nervous exhaustion the post-mortem rise in the temperature is slight, if met with at all.

Bernard's[3] celebrated experiments on the sympathetic seem also to support the theory that nerve force is directly transmutable into heat. This physiologist showed that section of the sympathetic trunk in the neck was invariably followed by a rise in the temperature of the cheek on the corresponding side of the body, a rise of as much as 11° above the temperature of the other side. He further showed that excision of the superior cervical ganglion or section of the cerebro-spinal nerves of the face on the same side did not materially change the result of the experiment. Now, how is this rise to be explained? By attributing it to an increase in the circulating blood of the heated parts? This explanation can scarcely be received, for Bernard tied the vessels and yet the high temperature continued. Moreover, the temperature of inflamed parts never approaches 11° above the normal standard; but in Bernard's animals the high temperature continued for months without the supervention of inflammation or any other disease. While in Sir B. Brodie's experiments on animals under the influence of woorara, which dilates the capillaries, it was shown that the temperature declined while the heart was beating steadily.

Dr. Carpenter,[2] while attributing the rise to an increase in the flow of blood through the parts, seems to be conscious of the insufficiency of the theory, for elsewhere, he says, "in some instances, however, such variations seem to be independent of changes in the supply of blood. Thus Schiff has shown that irritation of the sensory nerve in a dog under the influence of woorara and therefore incapable of performing muscular movements, causes increase of temperature of one or other of the hemispheres of the brain, and was independent of changes in the circulation since it occurred, even as late as twelve minutes after the heart's action had ceased. Even irritation of the nerves of special sense will produce this effect, for it was distinctly perceptible in a thoroughly woorarized dog, before which an umbrella was suddenly opened." If then a change in the circulation or respiration cannot explain the rise of temperature in these instances, why should it be adopted to explain the rise in Bernard's experiments when it cannot possibly explain it? and if transformed mechanical force (irritation) in the case of the one dog, and transmuted light (reflected from the umbrella) in the case of the other produced the rise, why should it not be received that conversion of nerve force into heat produced it in the animals operated on by Bernard? Nerve force supplied by the ganglia *directly before* the excision of the superior cervical ganglion and section of the cerebro-spinal nerves, and indirectly by anastomosis after the section and excision. The removal of one ganglion lessened the source of nervous supply; it lessened, but did not suppress it. The reader, who in thought, is not familiar with the transformations of force within the tissues may read the following with advantage: "A patient was for some time in the London Hospital, in whom there was such an undue impressibility of the retinæ that she could not remain in even a moderate light without a continual repetition of the act of sneezing." In this instance the physical motion named light became in the tissues of the eye and brain transformed into physiological motion muscular and other.

[1] Human Physiology, Smith's edition, p. 546.

In reviewing the facts above adduced it seems difficult to deny that there is some ground for the belief that heat, under certain circumstances and conditions, becomes directly transformed into nerve force or motion in the nervous tissues. The parallel instances of sound and light becoming nerve motion in the organs of sight and hearing, the phenomena of egg-hatching by artificial means, and of the restoration of animals senseless from excessive cold under the application of external warmth, as also of heat accelerating and cold retarding the development and growth of vegetables, and of the lower animals, the action of heat on hibernating animals, the experiments of Chossat illustrating the effect of starvation on animals, and above all the experiments of John Hunter on the absorption of heat by dead and living tissues collectively and individually support the theory that heat is directly transmutable into nerve motion. While on the other hand the theory that nerve motion is directly transmutable into heat is supported by the rise of temperature, in tetanus and epilepsy, in intermittent fever, in some cases of injury to the spine, as for instance that described by Brodie, in the bodies of those who have died from yellow fever, cholera, and other acute diseases, and in the cheek after section of the sympathetic trunk in the corresponding side of the neck.

I am not arguing to show that heat is the main source of nerve motion, or that nerve motion is the main source of animal heat, but only to show that there are facts which indicate or, at any rate, support the hypothesis that heat is one of the sources of nerve motion, and nerve motion one of the sources of heat. That nerve force is one of the sources of animal heat appears to me to be taught more or less distinctly in the writings of Le Gallois, B. Brodie, Schiff, Bernard, and Prof. H. C. Wood, but the general opinion is that animal heat is exclusively derived from chemical sources. Physiology is, and always has been, colored by the prevailing science of the time, and in this way its history is the reflected history of general science. In the course of its development, it has been metaphysical, mechanical, and chemical, while now its constitution is getting to be colored and invigorated by the adoption and assimilation of the principles of physics. That it should be so is unavoidable—nay, it is right—for physiology, in its completest form (if it ever attain to such perfection), must be the sum and embodiment of all sciences, and if we would find the truth, we must use the principles and facts of all sciences in explaining and harmonizing vital phenomena. No one saw this more clearly than Liebig, himself one of the creators of animal chemistry; so he expressly cautions physiologists against the misuse of chemistry in these words: "From the false notion which has been formed of the influence of chemistry on the explanation of the vital phenomena, it has happened that, on the one hand, this influence has been estimated too low, and that, on the other, the expectations and demands on it have been raised too high.[1]"

A CASE OF TRAUMATIC AMAUROSIS.

By OLAF PAGE, M.D.,

OF VALPARAISO, CHILI.

The patient, aged 40, a porter by occupation, gave the following history: Two months ago, whilst carrying a load down some cellar-stairs, he missed the last step, and fell violently upon the floor, striking his face and forehead over the left eye. He did not lose consciousness, nor did he have any vomiting. On the fourth morning after the accident, he awoke with his eye very much swollen, and with total loss of sight. He had a leech applied, and a week later applied for advice. I found both upper and lower eyelid so swollen that it was impossible to open the eye. The upper lid was of a dark, livid color, and, with the exception of a small portion in the middle, intensely hard. The ecchymosed conjunctiva protruded between the lids. I made a small incision into the soft spot, giving exit to a little pus. He was given a weak carbolic-acid lotion to apply to his eyelids. In a week or ten days, the eye had become soft enough to enable me to separate the lids. The conjunctiva, swollen and hard, had become attached to the margin of the lower lid, so that I was obliged to separate it with a knife. On examination, the aqueous humor appeared very cloudy, and the pupil irregular. The movements of the eyeball were pretty free in all directions. A solution of atropine, one grain to the ounce, was prescribed, to use but once a day only, as he complained of no pain.

As the swelling went down, and the aqueous humor became less turbid, I discovered a posterior synechia on the nasal side of the iris. The rest of the pupil was apparently quite free. Five weeks from the time of the accident, I examined him with the ophthalmoscope, and found a complete atrophy of the optic disk. Not a single bloodvessel was to be seen upon its surface. I could find no hemorrhages in any part of the retina.

The right eye the patient had lost ten years previously, probably from gonorrhœal infection. The stump, however, was entirely painless on pressure.

As the patient never suffered from any brain symptoms, the mischief was probably limited to the orbit alone, the blow having fractured the orbital plate, which, with the extravasated blood, must have cut off the blood-supply to the optic nerve.

Valparaiso, June 13, 1883.

MEDICAL PROGRESS.

Prophylaxis and Treatment of Cystitis in Women.—Prof. Küstner considers that many cases of cystitis in the female are due to a transfer of septic material from the vulva into the urethra and bladder by means of the catheter, and recommends that catheterization should not be done by touch alone, but should be aided by the eye. Further, the vulva should always be carefully cleaned before catheterization. It is highly important to have a clean instrument, and he considers this impossible with the instrument generally used. Even when it is boiled in carbolized water and cleaned with a brush, some material, more or less septic, will be found adhering to the eye, which cannot be reached by the brush, even when the catheter has a perforated extremity. He recommends a simple, straight glass tube of the size of an ordinary catheter, with a bevelled opening for introduction into the bladder. Küstner says that the curve of the female catheter does not correspond to the normal course of the urethra, which has been found by vertical sections to be either straight or sometimes S-shaped, never C-shaped, and consequently a straight tube will answer perfectly well. These catheters have been in use in Küstner's clinic for a long time, and no case of vesical catarrh has occurred since they first began to be used, although some patients have been catheterized as many as forty times after severe operations. The bevelled edge of the catheter is ground very smooth, and of course a catheter with a chipped place in the end must be thrown aside.

---

[1] Animal Chemistry, 3d Edition, p. 252, Gregory's translation.

Local treatment, washing out the bladder, is the best means of treating vesical catarrh. The ordinary instruments in use for this purpose, double-current catheters or T-tubes with India-rubber tubing, are insufficient for this purpose. Küstner uses a glass funnel-tube, somewhat like his catheter, into which a hollow stopper fits. When the bladder is full, the stopper is removed, and the urine escapes. For irrigation, he formerly employed weak carbolic solutions, but he now uses corrosive sublimate solution, 1 to 5000, giving not more than two irrigations in a day. By this means, severe cases of cystitis have been cured in two weeks. This funnel-tube and stopper are made by Otto Kloppe, Johannisplatz, Jena. [It may be pertinent to inquire why the stopper should be hollow if it must be removed when the urine is drawn.]—*Deutsche med. Wochensch.*, May 16, 1883.

Nussbaum's Treatment of Cancer.—Prof. Nussbaum noticed, several years ago, that indolent ulcers of the leg rapidly improved when an incision was made around them, at about a finger's width from their margin, and down to the fascia, the incision being prevented from healing. Not long ago he treated a case of cancer of the mamma, with so strong a tendency to hemorrhage, that each dressing of the ulcer threatened her life. As the patient was nearly moribund from the frequent loss of blood, Nussbaum surrounded the tumor with a strong subcutaneous ligature, which he drew together with all his strength, and then tied. The patient rallied completely. Not only was the hemorrhage arrested, but the tumor decreased to one-quarter its size, and the ulcer began to cicatrize. The patient's strength rapidly increased. Nussbaum, therefore, now proposes completely to prevent the feeding of these tumors by their peripheral nutrient vessels. The blood which supplies the tumor through its base is sufficient to keep it stationary, whilst it does not absolutely starve it. In order to accomplish the desired interruption of the supply from the periphery, Nussbaum urges the formation of a furrow around the tumor, down to the fascia, about one centimetre wide, not with the knife, however, but with the thermocautery. In the above-named case a tubercle had not been included in the ligature. Nine months after the application of the latter, this tubercle had grown, and had thus reached the tumor of the mamma, which tumor had meanwhile become quite solid. The tumor now began to grow again, and even to bleed. Nussbaum, therefore, surrounded all the isolated tubercles with a deep furrow, and their growth evidently stopped. Six weeks later they were still shrinking. Nussbaum thinks that the thermocautery or the actual cautery is much more useful than is generally believed. The subjective condition of the patients, their strength and appetite, are much better after an operation with the cautery than with the knife; the wound heals quicker, except in cases where approximation by sutures can be employed after knife operations; and relapses are much delayed. Nussbaum ascribes these advantages partly to the absence of loss of blood, and partly because the nerves and bloodvessels, being covered with cicatrix, are protected from the influence of the air.—*Physician and Surgeon*, July, 1883.

Uterine Fibroids Becoming Sarcomatous.—At the meeting of the K. K. Gesellschaft der Aerzte, of Vienna, on April 6, 1883, Prof. Kundrat presented two specimens of fibroid tumors of the uterus which had become sarcomatous. The first occurred in a woman, æt. 37, who had died of peritonitis from perforating round ulcer of the stomach. The tumor was situated on the posterior wall of the lowest part of the uterus and cervix, was about the size of an ostrich egg, filled the whole pelvis, and projected, by its smaller end, into the enlarged vagina; this portion having the microscopic appearances of a fibroid. Near it, in the posterior wall of the vagina, was a superficial ulcerated nodule as large as a walnut, and numerous metastatic points were found in the liver and both lungs.

The second patient was a woman, æt. 57, a victim to septic poisoning, after an attempt to remove the tumor by laparotomy. The tumor, half as large as a man's head, was situated in the posterior wall of a considerably hypertrophied uterus, with a prolongation between the folds of the left broad ligament. This tumor also contained, as did the first, a softened medullary spot of degeneration, but its original character was clearly shown.—*Medizinische Jahrbücher*, 1883, Hft. ii.

Rhabdomyoma of the Orbit.—Rhabdomyoma, or a tumor containing striated muscular fibres, is a very rare affection, and Dr. S. Bayer, of Stockholm, who describes a case of the kind in a recent number of the *Nordiskt Medicinskt Arkiv*, has met with only twelve instances of it in the course of his reading. His own case was that of a tumor extirpated from a little boy three years old, and which had been observed two months before the operation, penetrating between the globe of the eye and the lower eyelid, and pushing the former from below upward. The tumor was of an oval form, resembling a fibrous tumor in its consistence and in the appearance of the cut surface. On microscopical examination it was found that the neoplasm was chiefly composed of muscular fibres with transverse striæ, but that the greater part of these fibres had at the same time longitudinal striæ. These striæ were either pressed against one another, forming fasciculi arranged in different ways, or diffused in an intermediate substance rich in nuclei. At the points where the fibres are pressed against one another they interpenetrate by points. Caustic potash immediately dissolves the nuclei of the fibres, but causes the distinct appearance of the transverse striæ, while acetic acid causes the nuclei to appear clearly, but dissolves, although slowly, the transverse striæ. A longer treatment with caustic potash or acetic acid causes the dissolution of the whole, as happens in striated muscular fibres, which the striated elements of the tumors resemble, moreover, in this respect—that they present the same double refraction when examined by polarized light. An identical method of examination demonstrated the same property of refraction in the fibres of a tumor of a rhabdomyomatous nature preserved in the Pathological Institute of Stockholm. The mass which combines the muscular elements in the tumor now described by Dr. Bayer, is a delicate granular substance with round nuclei, which, with preparations of osmium, are dissolved in cellules provided with broad or slender prolongations, anastomosing with those of the adjacent cellules. As to the question of the origin of the tumor, the author can give no other explanation than by admitting the presence of fœtal muscular elements, which probably remained at the base of the orbit, and to the subsequent development of which the neoplasm now described was probably due.—*Med. Times and Gaz.* July 28, 1883.

Gelsemium in Submammary Intercostal Neuralgia.—J. Chéron states that a good many women suffer from a localized pain in the left infra-mammary region, which is due to uterine disease. In some cases it is so painful and persistent that the primary affection may be overlooked. More or less success has attended the use of quinine, aconite, morphine, atropine, the bromides, etc. Chéron has had good results from the use of the following: Tinct. gelsemium gtt. c, simple syrup ℥ij, distilled water ad ℥viij. S.—Dose, three to five dessertspoonfuls half an hour before meals, or three hours after. Sometimes there are extremely painful spots in the course of a nerve, and running back to the spine. These may be painted with tincture of iodine every three days.—*Progrès Méd.*, June 16, 1883.

Application of Iodoform to Peritoneal Wounds.—At the meeting of the Twelfth Congress of the German Surgical Society, Küster explained his method of making iodoform applications to the peritoneum, so as to obtain the full antiseptic action, and at the same time obviate the dangers of toxicity. In cases of ovariotomy, he wipes a sponge, which has been dipped in iodoform, over the coils of intestines, having taken care that all the superfluous powder has been shaken off, so that only a very thin film may adhere to the peritoneum. An iodoform plug is also placed in the vagina. In wounds of the face, about the genital organs, or in other situations where the ordinary antiseptic dressings cannot be easily used, he recommends iodoform collodion.

Among sixty cases treated by him in this manner, there was after-bleeding in only one, all the others having promptly convalesced.—*Deutsche med. Woch.*, No. 17, 1883.

Crotalus in Malignant Scarlatina.—Dr. John W. Hayward publishes the results of the treatment of two cases of malignant (hemorrhagic) scarlatina by crotalus. In the first case the symptoms were very aggravated on the second day. The throat was nearly closed, and she breathed with difficulty, with an occasional interruption, as though due to the swollen condition of the tonsils and fauces, which appeared softened, jelly-like, and as if gangrenous; the head was thrown upward and backward as far as possible; there was severe retching when anything was put into the mouth, even a teaspoonful of cold water provoked it, and the matter ejected consisted of dirty-brown mucus, apparently colored with disorganized blood oozing from the mucous membrane, or resulting from the gangrenous state of the fauces and tonsils, and there were some bloody streaks as if from blood forced out by the act of retching. After the retching she would fall back on the pillow, moaning in a very weak, low voice, as if dying; and she sank down into the bed in a state of stupid lethargy, like a dying typhus patient. The rash was only faintly visible, and the case apparently hopeless. He determined to try the effect of crotalus, which had been much recommended in the treatment of putrid and hemorrhagic diseases, when introduced subcutaneously as well as by the mouth. The cuticle was consequently removed from round the throat by a cantharides blister, and to the exposed cutis a wet compress sprinkled with crotalus was applied, and renewed at first after half an hour, and then every three hours, also a dose dissolved in a teaspoonful of water was dropped on the tongue every half hour. The effects were watched anxiously. There was no more retching after the first application of the crotalus to the denuded cutis, even when teaspoonfuls of beef-tea were put into the mouth; but the restlessness, pulse, and other symptoms continued much the same all the evening. During the night she gradually grew less distressed and dozed at intervals; toward morning she really slept, and the breathing gradually became less labored and irregular. On the morning of the third day the pulse could be distinctly felt, and was only 120, the respiration was becoming easy, the head was less thrown back, and the struggle appeared to be turning in her favor. The rash was now freely out on the body and legs, but it was of a purple color. The same medicine was continued internally, but now only every two hours, and the crotalus was no longer sprinkled on the compress. During the day the rash gradually brightened in color, and all the distressing symptoms receded rapidly, so that by evening she was able to drink with but little difficulty or pain; the respiration was almost normal; and the pulse was 100, and had gained considerably in force and fulness. From this time improvement went on rapidly, and on the ninth day she was well.

The same treatment was used on the brother of the patient referred to above, and with like happy results. Dr. Hayward has tested the drug again and again, and is thoroughly convinced that crotalus is a reliable remedy in this disease.—*Lancet*, July 14, 1883.

Diagnosis of Urethral Discharges.—P. Fürbinger, in a paper in the *Monats. für prakt. Dermatol.*, 1883, Heft 2, enters into a discussion of the differential diagnosis of the different discharges from the male urethra. 1. Spermatorrhœa is the unnatural loss of seminal fluid which regularly occurs during the act of defecation and at the end of micturition (without an orgasm). This condition, more common than is usually supposed, is not the first stage of morbid pollution. Gonorrhœa and sexual abuses are its most common causes. Spermatorrhœa will become azoöspermatorrhœa when the testicles cease to secrete spermatozoa, usually from epididymitis, when azoöspermia exists at the same time. 2. Prostatorrhœa is the discharge of the prostatic secretion, sometimes continuous, at others only during defecation and micturition. It is a rare condition, and a symptom of chronic prostatitis, usually following gonorrhœa. 3. Urethrorrhœa *ex libidine* is a condition usually seen in anæmic and nervous subjects, and consists of a scanty discharge, with strong sexual excitement and erection, but without ejaculation or orgasm. Of these conditions, two are recognized without difficulty. Spermatorrhœa is diagnosticated by the presence of large numbers of spermatozoa—a few signify nothing; and urethrorrhœa by its characteristic mode of onset. The secretion of urethrorrhœa, which comes from Cowper's and the urethral glands, is clear, stringy, and containing only a few epithelial and round cells. Azoöspermatorrhœa is characterized by an abundant discharge, and by the absence of pus-corpuscles, although their presence has no especial weight on the other side, as there may be a coexisting urethritis. In such cases, the diagnosis must be determined by the specific secretion of the seminal vesicles. If a jelly-like substance, resembling grains of sago in shape, be found, it is conclusive; if not found, it may be in solution, and will be precipitated by a concentrated alkali. The secretion is allowed to stand for some time, when a clear drop is placed on a watch-glass, and a drop of caustic potash added. If the drop shows a thick white cloud, or streaks, the secretion contains seminal fluid; if, however, it shows that there is no azoöspermatorrhœa, the diagnosis rests between prostatorrhœa and chronic gonorrhœa. In gleet the discharge is very scanty, drop by drop. In prostatorrhœa, digital examination of the prostate shows that that gland is painful on pressure.

The indications of prostatorrhœa are: 1. The presence, though not constant, of numerous amyloid bodies. 2. Numerous typical cylinder cells, especially if in the double-layer arrangement of glandular epithelium. 3. The large Böttcher's crystals, the presence of which is ascertained by mixing a drop of the secretion with a drop of a one per cent. solution of phosphorated ammonia on an object-glass. In about an hour, the crystals, numerous, large, and very beautiful, are found. The Böttcher's crystals are a constituent part of the prostatic secretion, and show that the prostate is involved. The prostatic secretion is not, as usually stated, a clear, odorless, thick secretion, but is thin, of a milky cloudiness, and has the characteristic odor of semen. The time at which the secretion appears in the urine is also a diagnostic aid. The first and last portions of the urine must be separated from the principal flow. If the secretion is in the first portion, gleet may be diagnosticated; if in the first and second, prostatorrhœa; and if in the last, azoöspermatorrhœa, which appears in the form of almost transparent, thick, ropy masses, and occasionally in the form of sago grains.—*Centralbl. für klin. Med.*, No. 16, 1883.

CAUSE OF THE HEART-SOUNDS.—DR. C. SANDBORG has succeeded, by means of a special apparatus, in producing an alternate dilatation and compression of the heart of an ox, and consequently imitation of the blood-current and play of the valves. The results show that the heart-sounds, the first as well as the second, are produced by vibrations which originate in the sigmoid valves. The first sound is produced by the vibrations which the blood-current, expelled in systole, produces on the free borders of the valves. The second sound is produced by the tension of the sigmoid valves from the arterial shock, at the beginning of the ventricular diastole. In order to demonstrate theoretically why the tricuspid and mitral valves are so constructed as to make no sound, when in the healthy condition, which is perceptible, Sandborg made the following experiments: 1. He fastened the auriculo-ventricular valves and left the sigmoid valves loose. 2. In another heart the right auriculo-ventricular and left sigmoid valves were drawn back, the mitral and pulmonary valves being left free. 3. In a third heart the aortic and pulmonary valves were fastened, the mitral and tricuspid being free. 4. In a fourth heart, the mitral and pulmonary valves were fastened back, and the tricuspid and aortic left open. These experiments showed plainly that both sounds of the heart could only be heard when the sigmoid valves acted freely, and nothing was heard when the auriculo-ventricular valves alone were free. Sandborg is now studying abnormal heart-sounds, and thus far has been able to reproduce double systolic and diastolic souffles.—*Revue Méd. Franc et Etrang.*, July 7, 1883.

SUPPRESSION OF SALIVA AFTER MUMPS.—MR. A. ST. C. BUXTON reports this case occurring in a lady of middle age. No sense of taste was retained, the mouth felt hot although the temperature was normal; there was intense thirst which was not relieved by drinking, and there was great difficulty in feeding her. Infusion of jaborandi, iodide of mercury, mouth washes of glycerine were equally inefficacious in provoking a flow of saliva. A silver probe was then introduced into the ducts successively, and the negative pole of a thirty cell Leclanché battery applied to the free end of the probe, the positive pole being applied to the nape of the neck. This proceeding produced a copious flow of saliva, which continued in the normal manner. Complete suppression of saliva in both parotids and submaxillaries is a very rare occurrence.—*Lancet*, June 23, 1883.

PREGNANCY AND PARTURITION WITH A CANCEROUS CERVIX UTERI.—PROF. MIDDLETON MICHEL reports the case of a woman, æt. about 30, the mother of several children, who, believing herself pregnant, consulted him with reference to a bloody discharge unattended by pain, which recurred whenever she had sexual intercourse. An examination revealed unmistakable disease of the entire neck, too extensive to permit of its excision, particularly as there were signs of pregnancy, of which she seemed quite sure. A saturated solution of carbolic acid and alum with glycerine was used as an injection awaiting the further development of positive pregnancy. There had been no suspicion of disease, as there had been no pain, and a bloody discharge only after connection. All coition was forbidden during the injections.

At the time of confinement there were no unusual symptoms. She was delivered in due time and without any especial inconvenience of a well-developed child. She herself survived only for three months, in such a state as not to have been able to take care of her infant.—*North Carolina Med. Monthly*, July, 1883.

At the meeting of the K. K. Gesellschaft der Aerzte, of Vienna, on May 11, 1883, DR. FELSENREICH related the history of a case in which pregnancy was complicated by carcinoma. The woman, æt. 30, was the mother of several children. She was admitted to the hospital at the end of the eighth lunar month. During the sixth month there was a period of five days' hemorrhage, but there was no other hemorrhage. On February 28th, there was an escape of liquor amnii, labor set in on March 1st, and on March 4th she was brought to the clinic (in the eighth month). The carcinoma had then extended over the infra-vaginal and middle part, and digital examination showed a stiff and friable condition of the cervical canal. Spontaneous delivery being regarded as impossible, with the consent of Dr. Braun-Ferwald, Dr. Felsenreich removed the carcinomatous growth, and thus made room for the delivery. A female child was delivered, and the placenta soon followed spontaneously. The uterus was then thoroughly disinfected and removed by the supra-vaginal operation, and the wound dressed with iodoform. On the third day urine escaped per vaginam. A carcinomatous nodule was found to be the cause of this, was removed, and the fistula closed. Two months afterward the woman was, to all appearances, well.—*Medizinische Jahrbücher*, 1883, Hft. ii.

CONSOLIDATION OF FRACTURES IN DIABETICS.—During the past eleven years, M. VERNEUIL has made four personal observations on this subject. The first case was one of compound fracture of the left leg; the second a fracture of the humerus in a badly nourished patient; the third a fracture of both bones of one forearm; and the fourth a fracture of the lower extremity of the radius. These patients were all diabetics. Though this is too small a number of cases from which to draw general conclusions, they tend to show the evil influence of diabetes on the formation of callus. In only one case of the four did the formation appear to be normal, and in the other three the formation was very defective. By a singular chance, these three cases represented the three different degrees of the same lesion—tardy consolidation, imperfect consolidation, and non-consolidation. In investigating the causes of these anomalies of the reparative forces, it is difficult to dispute the part that the dyscrasia must play, for in each of the three cases the fracture was easily reduced and kept in place by suitable apparatus. There was no fault to be found with the mechanical part of the treatment. No difficulty was experienced in keeping the small wound closed in the compound fracture of the leg, and there was no suppuration.

M. Verneuil concludes his paper with the following propositions: 1. The retardation and absence of consolidation found in the three cases seem to be due to diabetic dyscrasia. 2. This retardation and absence of consolidation necessarily imply a diminution or suppression of the reparative forces, and particularly of nutrition. 3. From these facts, we may conclude that diabetes, when it embarrasses or stops the formation of callus, does so, at least indirectly, by impairing nutrition.—*Gaz. Hebdom.*, July 27, 1883.

INTRAVENOUS INJECTION OF SALINE SOLUTIONS.—DR. L. SZUMAN reports a successful case of intravenous injection for anæmia after traumatism and operation. Besides this case, he mentions eight successes, and gives the following as the advantages of this therapeutic measure: 1. One can always get the requisite fluid. 2. The operation requires no special apparatus, as an injection apparatus and a canula or probe-trocar are always at hand. Thorough antiseptic precaution must be observed with regard to the instruments. 3. Saline solutions in cases of acute anæmia must supersede transfusion of blood.

Dr. Szuman's case was that of a boy, æt. 15, who had sustained a compound fracture of the surgical neck of the right humerus, with laceration of the capsular ligament, and fractures of the right femur and tibia. When seen, the patient was in a state of collapse, the face, lips, and conjunctiva bloodless, and he was almost pulseless. Szuman decided to resect the shoulder-joint, and chloroform was cautiously administered. The wound was dressed antiseptically. The collapse was so great, however, that artificial respiration was employed, the head lowered, and ether injected hypodermatically, with the result of rallying the patient. On the next day, the lips were blanched, he was very feeble, and rejected food. Vomiting set in in forty-eight hours. During a change in the dressing of the wound, convulsive twitchings came on, increased, and the patient became unconscious. As the patient seemed to be dying of cerebral anæmia, ether was again injected, the upper extremity lowered, the limbs rubbed with camphorated spirit, and the uninjured limbs bound with elastic bandages. Intravenous injection of saline solution was then made: ʒiss of common salt and grs. xv of carbonate of soda were dissolved in ℥xxxivss of distilled water. A carbolic disinfectant was employed, there being no transfusion apparatus at hand; a small drainage-tube was fixed to a fine trocar; this was inserted into the median vein (into which the canula was fixed), and the fluid injected until about ℥viij had been injected, when the patient opened his eyes, the spasms stopped, and he began to talk. After about ℥xxiv had entered the circulation, the pulse fell from 144 to 112, and he began to complain of being cold; the injection was accordingly discontinued, and the ligature removed from the vein. From this time, he steadily improved, and finally completely recovered.—*Berliner klin. Woch.*, No. 21, 1883.

TREATMENT OF PHIMOSIS BY DILATATION.—M. DE SAINT-GERMAIN considers dilatation as the best means of treating congenital phimosis, even in the adult. He uses Nélaton's dilator with three blades, but has successfully used Trousseau's double-bladed dilator. He thinks that dilatation is applicable to all cases of phimosis, except those in which the preputial mucous membrane is thickened and of almost cartilaginous hardness. The blades of the dilator are introduced as far as the base of the glans penis, the instrument opened, and the amount of the constriction produced on the mucous membrane of the prepuce is determined by the degree to which the instrument opens. When the double-bladed instrument is used, the dilatation converts the narrowed preputial orifice into a buttonhole slit, and a second dilatation completes the operation. It then only remains to break up the adhesions existing between the gland and the prepuce, and during the next few days the prepuce should be regularly drawn back, and the parts dressed with borated vaseline.—*Revue Méd. Franç. et Étrang*, June 9, 1883.

PATHOLOGICAL CHANGES IN COLCHICIN POISONING.—At the close of a paper on the pharmacological study of colchicin, DR. HEINRICH PASCHKIS thus summarizes the anatomical changes found after death: The lungs are, as a rule, pale, and contain but little blood. In only one case did the lungs contain much blood, and several times there were hemorrhagic spots on the pleuræ, absence of diarrhœa, with vomiting and cramps. The heart is seldom empty of blood; usually the right or both ventricles were filled with black thrombi. In one case, the pericardium contained a hemorrhagic spot. The peritoneum is generally injected, with small hemorrhagic foci here and there, the same condition being true of the diaphragm. The omentum also contains hemorrhagic spots. The spleen is generally contracted, wrinkled, bloodless, and the liver containing but little or no blood. The kidneys are pale; the cortical and medullary substance bloodless. The bladder is moderately contracted, containing a little urine. The mucous membrane of the stomach and intestines is reddened and markedly hyperæmic, with numerous hemorrhagic spots. Microscopic examination shows widespread extravasation in the submucous tissue and partial lifting up of the epithelium in the mucous tissue by small extravasations. These hemorrhagic spots are found in the whole of the intestinal canal and in the stomach, the folds of the mucous membrane being always prominent; they are frequent and large, except at the pylorus, which is always firmly contracted, and in the region of the ileum and large intestine; they are punctiform, striated, or streaked often to such an extent that the mucous membrane resembles coarse bluish-red cloth. The contents of the stomach are a clear to dark-yellow mucus, sometimes containing transuded blood. Finally, the membranes of the brain are hyperæmic.—*Medizin. Jahrbücher*, 1883, Hft. ii.

MICROBES IN THE LIQUIDS OF THE NORMAL ORGANISM.—MM. OLLIVIER and RICHET have recently made further investigations on the existence of microbial elements in the organic liquids of fish in the normal state. They have already found microbes in the lymph of the peritoneal, pericardial, and cerebrospinal cavities. Now they announce the discovery of these elements in the blood of fish, taken during life, and from the heart itself, with proper antiseptic precautions. Culture of these microbes has not caused putrefaction in clean, hermetically closed tubes, while the blood, placed in open vessels, has undergone rapid putrefaction. They conclude that the lymph and blood of fish normally contain microbial elements, of which the nature and development remain to be determined.—*Gaz. Hebdom.*, July 27, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, AUGUST 18, 1883.

CHOLERA PREDICTIONS.

THE panic caused by the rapid spread of cholera in Egypt is subsiding in the absence of cases in European ports, and the representatives of commercial interests are now inclined to think with Noah's neighbors of old, that "it isn't going to be much of a shower after all." Among others the United States Consul at Smyrna, Mr. W. E. Stevens, in his report of July 13th, adopts the theory, at first offered by British officials, that the Egyptian outbreak is not true Asiatic cholera, but a disease of local origin, due to bad sanitary condition and impure water supply. It is needless to occupy space with the arguments which he gives in favor of this theory, for by this time those who advanced it are probably satisfied that if the disease is not Asiatic cholera, it is not distinguishable from it as to symptoms, results, or power of infection. The chief argument in favor of its local origin is one that is always urged by a certain class in such outbreaks, viz., that there is no evidence of its importation.

Negative proof of this sort is proverbially weak and unreliable, and the fact that the Commission which visited Damietta in the midst of the panic of the first few days after the announcement of the presence of the disease, found, during the two days of its stay, no evidence of importation, is almost without significance. It would have been strange indeed, under the circumstances, had they found such evidence. At present the flame of the epidemic is burning lower, in some places for want of susceptible material, in others because of isolation and disinfection of the first cases, or because of some peculiarity in the local and atmospheric conditions.

To conclude from this state of things, however, that the danger is less, or has disappeared, is foolish. We have previously stated that it is improbable that cholera will reach the United States this year, but that it is an even chance that we shall have it next year. Since that opinion was published the danger has diminished very little, if any, and while there is not the slightest occasion for panic, there is very urgent need of enforcing cleanliness, of looking to the purity of water supply, and of great care in the administration of our quarantine stations.

HAY FEVER.

ALTHOUGH our title is a misnomer, the disease is a reality, and one which calls for careful study in view of the apparently ever-increasing frequency of cases of the disorder. Some years since, Dr. Wyman, of Boston, who has published by far the best book upon the subject, essayed a more definite and scientific appellative, and, were it not for the fact that very many cases appear in the early summer, "autumnal catarrh" would be the most appropriate title. But, as a matter of fact, many cases occur in the month of June, and some few have been observed by the late Dr. Beard in July, so that, to include all cases, the title of "Periodical Catarrh" would be perhaps best, and certainly most accurate. It may be, however, that, as in many other affections, usage will continue to apply the title whose only claim lies in antiquity, and that as many of us insist upon calling enteric fever typhoid, we shall continue to speak of hay fever, because it occurs at the time of hay harvest in England, and prevails at the same time, but long after that harvest is ended in America.

One thing is, however, certain, that there is an increasing number of persons who at one stated season of the year, somewhere between June 1st and October 1st, suffer from catarrhal attacks of greater or less severity, from which they are generally free at other seasons. In a large majority of cases the catarrhal symptoms are confined to the nasal and conjunctival mucous membrane, but in a considerable number there is a development of bronchitis with more or less well-marked asthmatic symptoms. Starting with the conjunctiva, and extending to the minute bronchial tubes, all the intervening mucous membrane is liable to attack, and the gravity of the symptoms of the disorder are in pretty exact accordance with the amount of mucous membrane involved.

But our object is not to write a treatise upon an affection notoriously unamenable to medical treatment, but merely to comment upon one or two curious, and as yet not satisfactorily explained, peculiarities connected with it.

One of these is the very evident increase in the number of cases. Further than the fact that, owing to the efforts of the United States Hay-fever Association, the disease escapes classification as an ordinary cold, and is recognized by the single element of its periodicity, there does not seem to be any sufficient reason for this increase. For while the affection attacks principally those well-to-do in life, there are numerous exceptions to the rule; and while many of those who suffer from it belong to the category of nervous individuals, very many others would never be classed as such, and but few give evidence of being the subjects of suppressed gout.

Quite recently, Dr. Harrison Allen and others have noticed a peculiarity in the anatomical position and shape of the inferior turbinated bone, which, to say the least, is frequently associated with autumnal catarrh; but such a peculiarity can in no way account for the periodical character of the affection.

So far as the present state of our knowledge extends, we are compelled to fall back upon that most unsatisfactory and shadowy cause—idiosyncrasy—acted upon by the inferred influence of vegetable matter. Attempts have been made by Blackley, Marsh, and others to fix upon certain particular pollens, as those of the grasses, maize, and ragweed, as the especially exciting cause; but it would rather seem that many varieties of vegetable dust are equally efficient. We are not aware of any observations which have connected the affection with bacteria; nor can we reasonably hope for any solution of the problem which neglects the *seasonable* existence of the exciting cause, although it can be readily seen that the idiosyncratic susceptibility to that cause may be anatomical.

While remedial measures can do much to alleviate the severity of the disorder, it is becoming pretty well understood that a cure can only be obtained by a flight to one of the localities which experience shows to enjoy exemption from the presence of the exciting cause. These localities are quite numerous, and are being annually resorted to by large numbers. The Hay-fever Association has published a large list of such places, and has placed its estimate upon their respective value, but these estimates are principally based upon lay opinion, and are subject to some qualification on the score of inaccurate observation. There seems to be no doubt that at some high elevations, and some low ones, relief is obtained. The essential point would seem to be absence of much upland vegetation. Thus it is that some portions of the White Mountains, and certain seashore resorts situated upon sandy islands entirely surrounded by water, as Fire Island, New York, and Beach Haven, New Jersey, have acquired their reputations, while many others upon the Association's list are probably of equal value. There is little or no doubt that upon the ocean itself the exemption is most perfect. Whichever locality is selected, it is important that the patient should go there early, if possible, before the beginning of the attack, and that a quiet and prudential life should be led.

Observation would seem to show that those who suffer most at home are best satisfied with the measure of relief obtained, although the actual exemption is more perfect in those who merely suffer from an annoying coryza and irritating cough at home. Experience would also seem to show that in some cases, at least, the regular and systematic resort to one of the favorable localities is attended with increasing benefit, although there appears to be no evidence that the tendency will ever entirely die out in adults. In children, it would seem to be most important that every effort should be made to keep the disorder in abeyance, by sending them early and regularly to a suitable location, in the hope that the habit of system may not become ineradicable, but may disappear before the advent of adult life.

THE COLLECTIVE INVESTIGATION OF DISEASE IN ENGLAND AND AMERICA.

The idea of collecting, combining, and analyzing the experience of a large number of those physicians who are engaged in general practice, is not by any means a new one; but until quite recently no definite, well organized attempt has been made to carry it into effect.

Individual efforts have been made here and there to obtain such information by means of circulars containing lists of questions, and when the querist has been a man well known to, and respected by the profession, some interesting results have been obtained in this way.

The organization of the Collective Investigation Committee of the British Medical Association marks a step in advance in this direction, and now that this Committee has proposed to the American Medical Association to join in the work, some account of the organization and methods of the English Committee may be of interest.

The matter was under discussion in the British Association for two years before the present organization was completed and work fairly commenced. The Collective Investigation Committee is a Committee of the general Association, and is charged with the duty of selecting the subjects to be investigated, and of preparing the questions to be sent out. The formulating these questions is one of the great difficulties in the work; it can only be done successfully by those who are fully conversant with all that is known with regard to the subject under consideration, and who can indicate briefly and clearly those points which are still doubtful or unknown, but which it is fairly probable may be settled if the attention of a large number of practitioners be called to them, and the results of their observations are collected, compared, and properly analyzed.

The method adopted by the Committee is to prepare, or have prepared by experts, a memorandum on the subject of inquiry, giving as briefly as possible the state of existing knowledge with regard to it, and to issue with this a card containing the questions to be answered.

For example, the memorandum on acute pneumonia, explains that the special point to be investigated is that of its etiology, and more particularly as to what grounds there are for supposing that it may sometimes, or often, or usually, be due to infection or to some more or less specific septic influence. It then goes on to explain the purpose of the individual questions, and the points to be kept in view in answering them. The card issued with this memorandum is accompanied with a specimen of a "filled up" card. It asks for the initials of the patient, the sex, age, occupation, conjugal condition, whether temperate, food; residence, whether high or low, etc.; atmospheric conditions; number of cases of the disease in the same house—in the same district; sanitary conditions of house and district; family history of lung disease, etc.

The memoranda and cards thus far issued relate to diphtheria, chorea, rheumatism, pneumonia, and syphilis, and while of unequal merit are nevertheless all good, and well calculated to produce good results.

Turning now to the machinery for placing these cards in proper hands, we find that this is done to a great extent by local committees of the various local, or, as they are called in England, "Branch" Associations.

The appeal of the general Committee for the formation of these local Committees sets forth the importance of the work, pointing out that a large part of our present knowledge of disease is derived from hospital practice in which little or no opportunity occurs for the observation of the conditions which precede established organic disease. It explains also the failure of previous efforts as due to the circulation of questions requiring complex and elaborate answers, usually relating to past and unrecorded experiences, and to the want of general interest in the subject.

At the recent meeting of the American Medical Association in Cleveland, Dr. Billings presented communications received from Dr. F. A. Mahomed, the Secretary of the General Committee of the British Association, inviting coöperation on the part of American physicians, and expressing a hope that this coöperation might be furnished in an organized and systematic way through a Committee of our own Association. The papers were referred to the Standing Committee of the American Medical Association, which is charged with the investigation of the relations of disease to climatic conditions, of which Committee Dr. N. S. Davis is chairman, and they will, no doubt, receive due consideration.

The advantages of extending the field of observation and inquiry over this country are sufficiently obvious, and it is a happy thought to provide objects of a common interest for the two Associations which will tend to bring the physicians of the two great English-speaking nations of the earth into closer relations with each other. The problems of English physicians are, to a great extent, our own problems also, and we can, no doubt, both help and be helped in this matter.

The English Committee already find the material which they have collected so abundant that they propose to publish it in the form of a semi-annual record. Perhaps this record may become a truly international one. No doubt there are some rather special difficulties in the way, but we think all these can be overcome by tact and perseverance. After all it is but the extension of the principle of association, and division of labor, which has in other fields produced such excellent results, and we hope that the Committee of the American Medical Association which now has the matter in charge, will be able to agree upon some plan which will be a practical acceptance of the invitation of the British Committee.

In the words of Sir William Gull, "This is the age of combinations, but there is none which has a better objeet than this; for what can surpass that whose purpose is the investigation of truth for the good of man?"

"MY ASYLUM LIFE."

Our attention has been attracted by an article in *Lippincott's Magazine* for July, 1883, entitled "My Asylum Life, by a physician." It purports to be an autobiographical account of a case of insanity, with criticisms on asylum management. Either it is fiction, written by a practised hand, in order thus artfully to attack the system pursued in asylums, or it is a true story. In either case, it is of interest to the physician, since even if it be untrue as a personal narrative, it exhibits a curious knowledge of the routine of life in hospitals for the insane, and would be, in any point of view, worth considering by those who have charge of them. On the whole, after carefully examining the evidence afforded by the narrative, we are inclined to believe it fictitious, although as to this there is and will be some difference of opinion.

The case is described as a rare example of double self-consciousness, involving, finally, when at the worst, a belief in the fact that the patient was himself and also Satan. As a statement of his own case by a recovered patient, the continuity of the psychological history and the accuracy with which, after years have passed, conversations are related, make rather too heavy a tax on our faith. At the same time, the analytic study of the case in its symptoms and the story of the rise and progress of a despotic belief in a delusion incline us to believe that in some sense the account is true, and that whoever wrote it must be much in contact with the insane.

In the patient's distress, he consults at least two physicians, and, of course, as a doctor, comments sharply on their views and manner. It is at the close of one of these interviews that his "Satan-self" threatens to infest him with other devils, on which the patient, in a moment of clearness, reflects that, although double personality is well known, for a man to regard himself as more than two persons is an unknown case, and, therefore, not to be feared. We should like to know if this be so.

The idea that "Sleep is a widely illustrated insane asylum" is scarcely new, and is, perhaps, rather too fanciful. But however curious may be the psychological study with its points of harmony and grim description of "pure terror" as a possible mental condition—a part of the case quite too dramatic in its presentation—the practical value of the article must lie if anywhere in its hints as to the evils and difficulties of asylum life.

The sharp comment on the failure of intelligent study and tactful treatment of cases during the first day or two after admission struck us, as well as the complaint as to the general incredulity in regard to the statements of those once insane, a point, we fear, but too well taken. We were impressed, too, by the remarks on the fact that the asylum doctor habitually believes asylums the place for all insane people, and that, in proof of this, we see no statements in their returns of releases within a day or two after admission of those whom they feel were best treated outside of stone walls.

The further comments on the diet, on the want of trained male nurses, on the insufficiency of medical care, the neglect of thephysical ailments of the lunatic, on the horrors of the lock and bar system, and the reasons for the frequent failure of asylums to secure the highest medical skill, are all alike the more valuable because of a certain charitable calmness with which the charges are made, while the pitiless sarcasm on the managers of asylums, and on the prevalent methods of inspection, might lead us back to the belief entertained by many in regard to this paper that it must have been written by one whose statements were emphasized by personal suffering.

But whether a sad and true story or a clever assault on asylum management in the guise of a fictitious sketch, it cannot fail to suggest how great would be the interest of a volume of autobiographical statements of cases of insanity, nor to awaken afresh the question as to whether the general medical opinion is correct in its belief that there is still much to amend in our care of the insane.

THE RIGHT OF AN AUTHOR'S OWNERSHIP IN HIS LECTURES TO BE VINDICATED.

Three weeks ago we published letters from Drs. Alfred Stillé and Hayes Agnew, denouncing as fraudulent *An Epitome of Medicine and Surgery*, published in this city by Samuel M. Miller, M.D., and purporting to be by them. We now learn that, upon their affidavits that the publication is unauthorized by them, the Court has just granted a preliminary injunction restraining the circulation and sale of this book. At the hearing, it is expected that the Court will give equitable relief to Drs. Stillé and Agnew by granting a perpetual injunction and damages.

Authors have been imposed upon so long by the unauthorized and even fraudulent publication of their lectures, that they finally began to believe that they had no right of property in them which piratical publishers were bound to respect, and these publishers in turn, in the absence of protests, gradually began to think that this apparent view must be practically correct. In the present case flagrant injustice has been done Drs. Stillé and Agnew, whose lectures have been stolen, for they are made to masquerade before the profession as authors of a treatise which they never wrote, and which they indignantly repudiate, and the case is particularly aggravated by the fact that Dr. Miller took out a copyright on the book without apparently the slightest shadow of authority.

We are very glad to learn that the common-law right of an author's ownership in his lectures is soon to be again vindicated in our courts, and we trust that this will stimulate our clinical lecturers to stop the publication of unauthorized reports of their lectures, which, by reason of the frequent errors and gross inaccuracies, have proved as great a fraud upon the reader as they were upon the rights and reputation of the authors.

In this connection, it affords us no little satisfaction to state that The Medical News has always acted in accordance with the view, which, over and again, has received judicial sanction, and that the lectures which have appeared in our columns have always been authorized publications, made by or with the express permission of their authors, and their right of ownership protected as well as acknowledged by the tender of pecuniary compensation.

PHENIC CAMPHOR IN THE TREATMENT OF ATAXIC TYPHOID.

Under this title, a French army surgeon, Dr. Amat, addresses a note to the editor of the *Bulletin Général de Thérapeutique* of a recent issue. His object is to inform the medical profession of the good results obtained from the administration of phenic camphor in low cases of typhoid fever. What is phenic camphor? When carbolic acid and camphor are rubbed up together with alcohol and water, a mixture results. The exact proportions recommended by Dr. Amat are the following: Camphor, 5 grammes (about 80 grains); crystallized carbolic acid, 2½ grammes (about 38 grains); alcohol, 150 grammes (about 5 ozs.); and water, 850 grammes (about 27¼ ozs.). This prescription is used by the stomach and rectum, and is reserved for the cases characterized by great depression, with nervous excitement. It is presented to our readers with the view that such a combination may offer some advantages in the class of cases above referred to.

SOCIETY PROCEEDINGS.

BRITISH MEDICAL ASSOCIATION.

Thirty-first Annual Meeting, held at Liverpool, July 31 and August 1 and 2, 1883.

Tuesday, July 31. Morning Session.

The fifty-first annual meeting of the British Medical Association was held at Liverpool on July 31st, August 1st, 2d, and 3d, under the presidency of Dr. A. T. H. Waters, of Liverpool.

Mr. Wheelhouse presented the

REPORT OF COUNCIL,

from which it appeared that the total number of members on the register on July 1st was 10,150. The revenue of the Association for the year was £19,076, and the expenditure and loss were £16,288, leaving a surplus of £2,788. The invested funds, exclusive of trust funds, amount to £13,267.

The Association then proceeded to the consideration of new by-laws, after which it adjourned.

Evening Session.

The members reassembled in the evening, when the President announced that the meeting was honored by the presence of several distinguished foreigners, amongst whom were Drs. Austin Flint, F. S. Dennis, and George M. Lefferts, of New York; Prof. Snellen, of Utrecht, and Prof. Tilanus, of Amsterdam.

The President, Dr. A. T. H. Waters, then delivered his

ANNUAL ADDRESS,

choosing for his subject the "Present Aspect and Future Prospects of Medicine."

He said: In considering the standpoint of medicine, we should always bear in mind that medicine must be judged by the therapeutic results which it achieves, and in proportion as we can show that the researches of the physiologist, the pathologist, and the chemist, and the application of scientific principles, have enabled the physician to deal more successfully with disease, to anticipate its development, to recognize its earliest symptoms, to mitigate its severity, and reduce its rate of mortality, so do we establish for our art a claim on the confidence and gratitude of mankind, and in this respect the present state of medicine shows no slight advance on the past, and promises a more rapid progress in the future. The past five and twenty or thirty years—not to go further back—have been marked by the general development of views with reference to many diseases, such as have largely and beneficially influenced our treatment of them. With regard to the affection which we term pneumonia, have we not seen the introduction into practice of a mode of treatment which has deprived the disease of much of its terror, and greatly reduces its mortality? Whatever be the views which we entertain of the nature of pneumonia, the important fact remains that we may enumerate amongst the successes of medicine of the present day, a large reduction in the mortality from the affection.

Again, the recent development of the practice of tapping the chest in pleuritic effusion—an operation comparatively rarely performed thirty years ago—is, in my opinion, a very marked improvement in therapeutics. Those who have carefully watched the progress of medicine in this matter, know full well how great have been the changes which have taken place within the last quarter of a century, and especially since the introduction of the aspirator. It is impossible to refer to all those to whom we are indebted with reference to this subject, but Trousseau as a pioneer, and Bowditch, whose large experience and satisfactory results exercised so beneficial an influence, I must not pass over, whilst there are many in this country to whom we owe no less a debt of gratitude. There is, perhaps, from the facility with which tapping may be performed, and the almost entire absence of risk when it is properly performed, a fear that it may sometimes be resorted to unnecessarily. But, from what I may term a somewhat large experience in the operation, I can speak with confidence of its value and safety in both acute and chronic effusions, and I cannot but think that, as the result of the early performance of the operation, we shall see, every year, fewer of those cases of deformed chest which so frequently follow neglected pleuritic effusion.

It is impossible to enumerate the various affections in which there is a marked improvement in treatment, and those which I have referred to must be considered simply as illustrations of my position; but whilst I speak with satisfaction on this subject, I must not forget to mention that, in the midst of many successes, we have instances of, I will not say actual, but comparative, failure. Our knowledge of the pathology of some affections remains very imperfect, and our therapeutics are in some respects very unsatisfactory. Although rheumatic fever is one of the most common diseases, it must be confessed that we are ignorant of its pathology. During the past few years there has been introduced into practice a mode of treating the disease by the compounds of salicylic acid, which has met with general adoption, and has been largely successful. I can add the testimony of my experience in its favor; but still, with all the opportunities which we possess of studying the affection, we are as yet unable to give any satisfactory explanation of its essential nature. But, gentlemen, of all the questions which now engage the attention of the pathologist and physician, there is no one which surpasses in importance that which relates to the dependence of certain diseases on micro-organisms. The subject is one of the greatest possible interest, and fraught with bearings of a practical character which already have had, and are doubtless destined still further to have, a vast influence on the prevention and treatment of disease. The establishment of the fact that pebrine, chicken-cholera, and splenic fever depend on the presence of specific microbes, and that relapsing fever has associated with it, if not indeed causing it, a like organism must be classed amongst the most striking discoveries of the present day, and undoubtedly mark an epoch in the history of pathological science; whilst the gradually accumulating evidence that tuberculosis is the result of a parasitic element seems likely to lead to its being placed in the same category as those affections the pathology of which appears now to be clearly established. Moreover, the brilliant results which have followed the process of attenuative culture of the virus of some of the affections to which I have referred, and the protective influence of vaccination by these attenuated fluids, as carried out by Pasteur, lead us to hope that, by further researches in the same direction, we may yet discover some means for checking the ravages of tuberculosis and other allied diseases, as certainly as the great discovery of Jenner has enabled us to check the ravages of smallpox.

Of the many problems which await solution in connection with the subject which I have just considered, no one is more pressing than that of the dependence, or otherwise, of pulmonary consumption on the bacillus which has been so largely found, not only in the morbid deposits which result from the disease, but in the expectoration of phthisical patients. Should it be found that in all cases of genuine tubercular phthisis the bacillus tuberculosis is present, and should future researches show that the disease is caused by the parasite, a solidity will be given to the pathology of the affection, and perhaps the therapeutics of it will be materially aided. Speaking from clinical experience, I cannot but conclude that the disease to which we give the name of phthisis has more than one mode of origin. Further investigation will perhaps clear up the doubt which exists on this point; and here I should like to observe that there are some affections of the lungs which closely resemble, in their clinical features, acute phthisis, and yet which, under careful treatment, do not go on to a fatal issue. Of such cases I have now seen several. Their general symptoms, their physical signs, their temperature-ranges, made me conclude that I had to deal with cases of acute pulmonary tuberculosis, and I have expected a fatal result, but recovery has taken place. These cases occurred before attention was directed to the presence of bacilli in the sputum of phthisical patients, and no examination of this secretion was made. In instances of a similar kind, we shall now be able to use this method of investigation, and possibly it will afford a valuable means of differential diagnosis, and enable us to give, in cases where the bacilli are absent, a more favorable prognosis than the general symptoms would otherwise warrant. I may say, in regard to the cases to which I have referred, that they were treated by free nutrition. the administration of quinine, and a somewhat liberal quantity of alcoholic stimulants.

The great point which remains to be decided, and which I hope the discussions which will take place at this meeting will help to decide, is whether the so-called bacillus tuberculosis is the cause or the consequence of the tuberculous disease.

Wednesday, August 1st.

The President of Council stated that a cordial invitation had been received to hold the next meeting of the Association in Belfast, and he moved that the invitation be accepted, and that Dr. Cuming of Belfast be appointed President-elect. Unanimously adopted.

Mr. Reginald Harrison then delivered the

ADDRESS IN SURGERY.

After expressing his high appreciation of the honor conferred on him, he referred to the surgical traditions of Liverpool, and then dwelt upon some of the more recent advances and work in connection with the surgery of the urinary organs.

He said, commencing with the kidneys, we are at once struck with what surgery is doing for them. Until quite recently the diseases of these organs were regarded as belonging almost exclusively to the province of the physician, and probably they would have remained so had preventive medicine obtained fuller development.

A more extended acquaintance with the pathology of the kidney has brought to light conditions in which the work of the physician requires to be supplemented by that of the surgeon. Pain arising from an undue mobility of the organ, tumors, deposits, hemorrhages, and collections of fluid within it—all these morbid states are now recognized as capable of relief or cure by fixing, opening, or extirpating the abnormal or disordered organ; whilst numerous illustrations have already been afforded of the successful removal of stones from positions where they must have ultimately led to the disorganization of the kidney in which they had become impacted.

It would be premature at present to endeavor to formulate anything like precise rules in reference to the application of the various operations on the kidney to which I have briefly referred; they are at present comparatively new to us, and we must occupy ourselves in cautiously moving in the direction they indicate, and in collecting experience rather than in drawing conclusions other than very general ones.

Amongst many valuable contributions to the literature of this subject which have appeared, I would include one by Dr. R. P. Harris, of Philadelphia, which contains an analysis of one hundred cases of nephrectomy. From this, as well as other communications which have more recently been published in this country, we may draw at least three conclusions of value, so far as the operation of extirpation of the kidney is concerned. These are:

1. That nephrectomy has been the means of saving many lives under circumstances where no other method of treatment was likely to be of service;

2. That this operation has been practised in cases where the probability of a successful termination appeared to be very remote; and

3. That a method of effecting the removal of the organ different from that which was selected, or a procedure less heroic, might, in some instances, have tended to increase the chances of success.

In these directions then—in selecting cases for operation, in rejecting others as unsuitable, and in determining relatively to the case in question the best method of procedure—I take it that good work has yet to be done.

It appears to me that among the difficulties we have to contend with in the application of nephrectomy, two stand out prominently: (1) The kidney it is proposed to remove may be the only one; (2) the opposite organ may be similarly affected, though in a less degree, yet sufficient to interfere with those compensatory changes being carried out which are essential when one excretory organ has to supply a lack of service on the part of another. The literature of this subject will already be found to illustrate the class of difficulties to which I am referring.

Till a few years since, the removal of stone from the bladder by crushing had been conducted on the lines laid down by Civiale some half-century ago. Though this method of proceeding has included amongst its advocates, past and present, surgeons of eminence, it cannot be said that, as then practised, it was either gaining ground or confidence. Indeed, I think I may say there was an increasing tendency to limit its application, and to substitute lithotomy in all cases but those of the simplest kind. The mortality consequent upon retention of broken calculi within the bladder was sufficient to induce all but the most ardent admirers of lithotrity to hesitate to give it the preference over a proceeding in which, whatever might be the risks, there was at least a guarantee that the whole of the stone had been removed.

Whilst the surgical mind was thus to some extent in doubt as to the limits to which the crushing operation of stone might safely be pushed, two important communications followed rapidly upon each other. That both of them should have emanated from America merely indicates that the desire to advance the art of surgery is not limited to the old country, but is a natural outcome of advancing civilization and humanity.

The first of these papers was by Dr. Otis, of New York, who demonstrated beyond all reasonable doubt, and in a manner which had not previously been attempted, that the male urethra was capable of safely receiving far larger instruments than were generally employed. Following upon this, and probably influencing the views of the author, came Dr. Bigelow's paper on the removal of stone from the bladder by crushing, and withdrawing it at a single operation; the latter communication clearly showing that the bladder was tolerant of much more prolonged manipulation than had previously been believed.

It appears to me that the originality of Bigelow in no way detracted from the importance of the work that had previously been done in this country and elsewhere, or compromised the acumen of those who were most interested in the progress of this department of surgery.

Passing to tumors of the bladder, it is not surprising, seeing what has been done for tumors of the ovaries, uterus, and intestines, by Sir Spencer Wells, Keith, Lawson Tait, Treves, and others, that growths occupying the interior of the bladder should have received special attention. Though the literature relating to this subject has been of a somewhat fragmentary character, such compilations as Stein's recent work, *A Study of Tumors of the Bladder*, conclusively show that some gratifying results have already been attained in both sexes. The great distress connected with this class of growths, the uncertainty as to the precise nature of the affection, in the first instance, and subsequently the kind of symptoms that accompany it have naturally suggested the employment of means having for their object their removal by operation.

Sir Henry Thompson has done good service in giving prominence to the employment of digital exploration of the bladder, and in furnishing illustrations of the great advantage that this proceeding is capable of affording in suitable cases.

From a consideration of some of the extremely valuable records which have been published by various surgeons, where the bladder has been opened for the removal of tumors, it appears to me that it might have been better had the operative proceeding terminated with the detection and exploration of the growth by the finger. The chief dangers which experience has shown to be liable to attend the performance of this class of operations are:

1. The chance of rupturing a bladder, the coats of which have been rendered less resisting than natural.
2. The provocation of a hemorrhage which it has been found difficult to control.
3. An incomplete removal of the growth.

On the other hand, an examination of many tumors of this kind, of which villous growths or tufts furnish the best examples, shows that there is nothing in their connections or relations which need necessarily interfere with their complete removal. Precise information as to the presence and attachments of these growths we may now obtain with comparative safety. Whether their removal is to follow upon their discovery will be matter for further consideration.

It appears to me that enlargement of the prostate is specially interesting to us in relation to its earliest and to its most advanced forms, and it is to these points that I shall more directly refer.

I have long been led to believe that our treatment of prostatic stricture—or by whatever name we know it—commences, as a rule, far too late; we delay until the bladder shows, by the formation of a pouch, or a saccule, behind the prostate, the first bad influence of back-pressure before we seek to rectify it.

I have endeavored to prove how much good may be done by the adoption of judicious mechanical treatment on the appearance of indications that the prostate is commencing to obstruct micturition, and I have founded my suggestion upon a condition which may be seen illustrated in any museum, viz., one in which, though the gland has become large, obstruction has not been known to occur. An extended adoption of this practice has convinced me that the pressing symptoms connected with an enlarging prostate may be kept in abeyance by the timely employment of those principles of treatment which are generally recognized as being applicable to any tubes within the body which are threatened with occlusion, and are within our reach.

In the more advanced forms of prostatic enlargement, where the bladder has been converted into a receptacle little better than a chronic abscess in which urine stagnates, surgery has done much to afford relief.

When the comfort that catheterism is capable of affording has ceased to be effectual, other plans of establishing a drain for the urine are at our disposal. It is not necessary that I should discuss the various means of effecting this; let me, however, say a few words in reference to two which have more recently come under notice: these are—first, incision into the bladder from the perineum; and, secondly, paracentesis through the enlarged gland.

For the purpose of securing a more or less permanent channel for the escape of urine from the bladder, other than by the urethra, I must admit that, following the practice of Syme, and to some extent of Edward Cock, I have a decided preference for an incision through the perineum, on the twofold ground of safety and comfort. We have had numerous examples of the great benefit that cystotomy is capable of affording for bladder affection dependent on a large prostate, none perhaps more striking than the case narrated by Mr. Lund, on the memorable occasion of the meeting in London of the International Medical Congress. The paper closes with this observation: "I have thus placed on record this case, unique in its character, and interesting and encouraging in its results, with the hope that should a similar case occur to any surgeon now present, he will not hesitate to give his patient the chance of benefit from a course of procedure so simple in its nature, and so likely to be followed by temporary, if not permanent, benefit."[1]

I may be permitted here to submit to your notice a method of puncturing the bladder through the enlarged prostate which has afforded very gratifying results. It consists in passing the trocar through the gland, and retaining it in the perineum, so as to afford a permanent as well as a convenient drain for the urine. I should have had more diffidence in commending this operation to your notice, had it not received the approval of our distinguished Associate, Prof. Gross, whose contributions to the surgery of the urinary organs are held in deservedly high repute on both sides of the Atlantic.

---

[1] Trans. International Medical Congress, vol. ii.

Though the primary object of cystotomy, as usually practised, is merely to place the bladder at rest by providing a continuous drain for the urine as well as the products of cystitis, it occurred to me, as it had already done to others, that it would be possible to extend this proceeding, with the view of removing those barriers to micturition which the hypertrophied gland so frequently presents.

It was to meet conditions such as these that Mercier introduced and practised division of the prostatic bar by means of a cutting instrument introduced along the urethra. This plan, though admirable in its conception, was open to the objection that in its execution it was necessarily uncertain, there being no means of surely ascertaining that the section was confined to the obstruction to be removed. On carefully considering the position of matters, as well as the proposals that had been made, it appeared to me more reasonable to attempt to divide the prostatic obstruction at the neck of the bladder from an opening made into the membranous urethra, than by means of instruments which had to traverse the whole length of the canal. I have recently brought under notice a case[1] in which I thought it desirable to explore the prostatic urethra from an opening made in the perineum, and through which I was enabled to divide, with precision, a prostatic barrier. The division of this portion of the gland was followed by complete restoration of the power of micturition, and has so far proved of permanent advantage.

The proceeding which I have thus put into practice seems first to have suggested itself to Mr. Guthrie, but I cannot find that he ever employed it. That it is not identical with the somewhat extensive incision of the prostate as for lateral lithotomy, which was practised by Sir William Blizard, is at once obvious. Its aim is to divide the obstruction—and the obstruction alone—by an opening so planned as not to expose the patient to undue risk, whilst, at the same time, it is capable of affording the greatest amount of room for manipulation by an extension of the incision, should this be found to be necessary.

I need hardly observe that a proceeding of this kind should be undertaken before the bladder has passed into a condition of confirmed and irremediable atrophy, otherwise, though we may succeed in removing an obstacle to the introduction of the catheter, our prospect of restoring the power of micturition will be as hopeless as it has proved to be under somewhat similar circumstances, where the operation of lithotomy has been undertaken.

It is impossible to avoid the conclusion, from their examination after death, that many atonied bladders might have been prevented becoming so by the timely removal of the obstruction by which a condition of permanent paralysis was induced and maintained.

The operative treatment of the enlarged prostate, when it obstructs micturition to a degree that cannot be met by judicious catheterism, is yet, I believe, open to considerable improvement.

Though the literature relating to either complete or partial excision of the prostate is very limited, there is much in it of promise. In one case, where I extirpated the whole gland for malignant disease, the benefit that followed far exceeded my expectations. It was that of a middle-aged man who, by reason of a carcinomatous prostate, was threatened with a speedy and painful death. I cut down upon the gland in the median line, and succeeded in enucleating it tolerably clean with my finger. I saw this patient eight months afterwards in very fair health, and quite able to go about his business. So far he has enjoyed an immunity from the symptoms which induced me to perform this operation, and though his disease is a malignant one, we have every reason to be content with the results obtained.

Then we have numerous examples where considerable masses of the prostate have been removed with very great advantage, in the course of operations on the bladder. Amongst these I would specially mention an important case by Mr. Bickersteth, and, more recently, another by Dr. John Ashhurst, of Philadelphia, in which the whole of an enlarged third lobe was successfully removed.

Cases such as these seem to favor the hope that operative surgery will be found capable of affording more relief to exceptional instances of this kind, and of extending to the large prostate the treatment which, in some degree, is applicable to other deep-seated growths.

In opening the Section of Obstetric Medicine **DR. GRAILY HEWITT** said: I take advantage of this opportunity to present a few observations on the question of food in obstetric and gynæcological practice.

There are certain terms in general use by the public, and by the profession, which are often employed in a vague, unmeaning, and indefinite manner—such as "weakness," "delicacy," etc.—whereby it is intended to designate a condition very frequently met with, but the essential nature of which is, as my experience has shown me, very imperfectly apprehended.

Another conclusion is, that the "weakness" is associated with and caused by a long-continued inadequate dietary, and that it is essentially what may be termed "chronic starvation." The rational view of the matter is, that this "weakness" is in the very large majority of cases preventable; that it should be regarded as the first stage of a serious possible disease; that it is mostly the result of chronic starvation, that it is curable, to a greater or less degree, in most cases, and that it is of the highest importance that it should be formally and carefully treated, as other diseases are, instead of being allowed to smoulder on until the constitution is thoroughly undermined, or until some ailment distinctly classified in our nosology makes its appearance.

It is a remarkable circumstance that so little as yet seems to have been done in the investigation of the effects of an insufficient dietary, looking at it from the quantitative point of view, although the effects of complete deprivation of food are well known. The popular impression is, that some people do not require so much food as others, and consequently, important diminution in the supply often escapes attention. I have to state the important conclusion, that a continuous insufficiency of food, or what may be termed a "chronic starvation," more or less intense in different cases, was found to have existed almost universally. Consequently, I have naturally been led to consider chronic starvation as a most important factor in disease, certainly in those classes of cases which have come more particularly under my notice.

It will be well to cite a few typical instances:

1. A young married lady, aged 24, consulted me for a severe retroflexion of the uterus, which appeared to have set in shortly after her first labor, some months previously. She underwent treatment for this affec-

---

[1] British Medical Journal, June 9, 1883.

[1] Trans. Royal Med.-Chir. Society, 1882.

tion; and, in the course of it, one day her mother came with her, and inquired of me why it was that her daughter had become liable to this affection. I replied that, in all probability, it was due to a previous condition of weakness, and insufficiency of meat as an article of food. "Yes," said the patient, "that is very likely true; for when I married, and could please myself, being very fond of sweets, I took little ordinary food during the first year, but lived chiefly on sweets, and ate little or no meat at all."

2. A young lady, aged 18, suffered much from menorrhagia, and her condition became finally one of complete inability for exertion. It was ascertained that this patient had lived regularly as regards her diet, but that her diet consisted principally of bread and puddings; and, having a marked aversion to meat, she had taken very little for two or three years previously; and it is the fact that I was afterwards consulted by two of her sisters presenting uterine symptoms, and with a corresponding history as regards the previous dietary.

3. Again, a young lady of very active habits, but who hardly ever took meat, became very ill after an unusual exertion, was affected with severe sickness, which went on unchecked for nearly a year, and was finally so ill that her life was despaired of. Here, the previous dietetic deficiency was most marked. The patient was finally completely cured, the sickness being found to be a reflex symptom dependent on a uterine displacement.

These cases might be multiplied *ad infinitum*.

I have been much interested in observing, also, the effects of previous insufficiency of food in apparently predisposing patients to attacks of puerperal septicæmia. In the cases of this disease which I have seen in consultation, I hardly recollect having seen a case where the patient so affected had, during the pregnancy, lived fairly well; and the worst cases have been those in which the patients fed badly and insufficiently during the pregnancy, and had been fed on a gruel diet after the labor was over. In cases where severe sickness during the early part of the pregnancy prevents the proper nutrition of the patient, the system is liable to become much impoverished, and an insufficient dietary may be, and often is, the preliminary to a dangerous childbed.

With very few exceptions, and those exceptions only tending to prove the rule, it is, I hold, impossible to find patients suffering from chronic uterine disease, who have not undergone, at some former period, what may be termed a starvation process, and careful inquiry generally elicits the fact that the quantitative deficiency in the diet extended over a considerable period. In many cases, the patients are found to be still under the influence of a deficiency in this direction, and to be "eating," as the expression is, "next to nothing."

The period of life during which quantitative deficiencies in the dietary are most common, is the two or three years immediately following the arrival of puberty. The girl is at school probably, her appetite is bad, or the food is not palatable, or is deficient in important particulars, or, as I have found in some cases, she eats little in order to keep thin; the strength fails, the appetite diminishes, and a habit of taking little is formed—particularly little animal food is taken. Three or four years of the most critical stages of life are thus passed, a time at which the body should be growing fast, and to maintain this growth in adequate vigor large supplies of nutritious material are required, instead of which the supply is far below the normal standard. The result is a general impairment of vigor and of vital action. On the generative organs, the effect is, as I have observed in numbers of cases, most decidedly injurious; and the effect, in most instances, is of this kind, that the tissues of the uterus lose their normal firm healthy consistence. The further result is that the pelvic organs as a whole, but particularly the uterus, undergo a subsidence in the pelvis; the uterus becomes liable to change of shape, and other alterations, more or less marked, in different cases. Slight exertions, slight accidents, or even moderate exercise, are, under these circumstances, liable to act most prejudicially on the softened and weakened contents of the pelvis. This is a faithful description of what I have observed to occur in very many cases. I refrain from pursuing the further history of patients so affected, as not falling within the scope of these remarks.

It is generally admitted by authorities on the subject of diet that nitrogen is the most essential of all foods, and that a certain amount, about three hundred grains, should be taken daily. In cases of chronic insufficiency of food, it appears that the diminution in quantity of food most frequently affects the nitrogen. Meat is the article of diet which, as a rule, is the source of the greater part of the needed amount of nitrogen. Milk is, of course, a most valuable alternative food; but, in these cases of absence of sufficient meat, we do not find it has ever been taken in any such quantity as to make up for the deficiency; and the quantity of bread consumed, even supposing it to be pure and of good quality, is in such cases entirely inadequate to supply the required quantity of nitrogen. I need not allude to the effect of deficiency in the other constituents of the diet. It is sufficient for my present purpose to show that the nitrogenous elements, while they are of all the most important, are those which are markedly absent in the cases now under consideration.

There are few observations bearing on the subject now under discussion which can be quoted from published works. Professor Voit (*Untersuchung. der Kost*, Munich, 1877) mentions an interesting fact. In a public institution, a home for girls, in which, he reports, the diet included an average quantity of one hundred and seventy grains of nitrogen only, the girls appeared healthy, but their muscles were found to be weak, and menstruation was found to be delayed in many cases until the sixteenth or seventeenth year.

Parker states that when this nitrogen is reduced to from 70 to 100 grains daily, the body gradually lessens in activity, and passes into a more or less adynamic condition, which predisposes to the attacks of all the specific diseases, especially malarious affections, typhus, and pneumonia, etc.

It must be assumed from what is known that if the minimum quantity of nitrogen—which, for the sake of argument, we may put as low as 250 grains in the case of a young woman—be not given, a condition of weakness will soon be induced, and with greater or less rapidity, according as the quantity of nitrogen falls much or little below this 250 grains *per diem*. Thus it is easy to understand why, in a year or two, with an average daily consumption of only 100 grains of nitrogen, for instance, important modifications of the nutritive processes are effected, whereby there is produced a direct predisposition to disease.

It is now some sixteen years ago, since I publicly discoursed on the importance of nutrition in the treatment of disease. I have made it the basis of my practice for some years past, and four years ago I described the condition to which I have now again referred as "chronic starvation." In the United States, Dr. Weir Mitchell has employed a system of rapid feeding, assisted by massage and electricity, for the cure of weakly, nervous sufferers, a system which has been found most successful, and Dr. Playfair has done good service in introducing Dr. Weir Mitchell's method into this country. The method in question is essentially a rapidly acting means of introducing nutritive material into the system, and it is dependent for its success on the fact that the principle of the curative influence and action of food is adequately recognized.

It is probable that it will be found, on further investigation, that particular deficiencies in the dietary result in deterioration of particular tissues of the body. The field for inquiry in this direction appears to be a large one. Deficiency in the quantity of meat taken, certainly, according to my experience, appears to have an enormous influence in predisposing to uterine ailments; but, no doubt, other organs of the body also suffer from deficiency in this article of diet. And I have abundant evidence that it plays a very prominent part in predisposing to the serious wasting diseases so often fatal in this country. I refrain from dilating further on this particular point, because such discussion would in this place be inappropriate.

The conclusion which is obviously suggested by the foregoing considerations, is the necessity for a greater attention to the question of diet, in the bringing up of families, than appears at present to be given to it. We all know that health and a good appetite usually go together. But it seems to be too frequently the case that, when the appetite is absent, such absence is taken as a matter of course, and receives no notice. It results from what has been stated, that absence of appetite may lead to most serious results. It is not immediately dangerous, but it is the first step, possibly, in the downward course. A continuously bad appetite constitutes a grave condition, and should be seriously regarded.

SIXTH ANNUAL SESSION OF THE AMERICAN SOCIETY OF MICROSCOPISTS.

Held at Chicago, August 7, 8, 9, and 10, 1883.

(Specially reported for THE MEDICAL NEWS.)

TUESDAY, AUGUST 7TH, FIRST DAY.

THE meeting was called to order by DR. L. CURTIS, President of the Illinois State Microscopical Society, who welcomed the guests.

The President of the American Society, PROF. A. MCCALLA, in his reply, commented upon the growth of and increased interest taken in the Society. He suggested that a good part of the time be devoted to practical demonstrations, and mentioned that the Royal Microscopical Society of London had honored this Society by making its President a Fellow ex-officio; in response to which courtesy the Society should take action.

A recommendation by the Executive Committee, that the by-laws be so amended that any part of the proceedings might be published in any reputable journal, provided that due credit be given to the Society, was adopted; and numerous new members were elected.

In the afternoon, DR. F. M. HAMLIN, of Auburn, N. Y., read the first paper upon the

MICROSCOPICAL EXAMINATION OF SEMINAL STAINS ON CLOTH.

He found by observation that the method of Koblank, viz., to soak out the stains with water was unreliable, since the water disintegrates many, if not most, of the dried spermatozoa. Finding that most fabrics upon which spermatozoa are apt to be dried are more transparent than is usually supposed, he recommends the following procedure:

1. If the stain to be examined is upon any thin cotton, linen, silk, or woollen fabric, cut out a piece about one-eighth inch square, lay it upon a slide previously moistened with a drop of water, and let it soak for half an hour or so, renewing the water from time to time as it evaporates. Then with a pair of needles unravel or fray out the threads at the corners, put on the glass cover, press it down firmly, and submit to the microscope.

2. If the fabric is of such a thickness or nature that it cannot be examined as above, fold it through the centre of the stain, and with a sharp knife shave off the projecting edge thus made, catching upon a slide moistened with water the particles removed. After soaking a few minutes—say five to ten—the powdery mass will sink down through the water and rest upon the slide. The cover-glass may now be put on, and the preparation examined.

The latter plan serves as well for hairs, but great caution must be observed in cutting them, lest the portions bearing the suspected deposit fly away and are lost.

The stained cloth can be twisted and rolled between the fingers to a considerable extent, without destroying the dried spermatozoa.

In the discussion, various members stated their experience in the examination of seminal stains.

DR. GRADLE mentioned that spermatozoa can be stained like micro-organisms, which fact does not seem to be commonly known. Drops of the fluid containing them are dried into a film upon the cover-glass, drawn through a flame, and then stained with a solution of magenta, or some other aniline color, and washed. The spermatozoa attract the eye by reason of their intense staining.

DR. STILLSON asked at what age the secretion of seminal fluid began, which question could not be answered with precision.

A paper by MRS. SARAH WHITING, of Wellesley College, on

COLLEGE MICROSCOPICAL SOCIETIES,

was read by President McCalla, who stated that it was the first contribution to the Society by a lady. It dwelt upon the utility and practical arrangement of microscopical societies amongst college students, based upon six years' experience at Wellesley College.

A paper prepared by Prof. Simon H. Gage, of Cornell College, on *Cataloguing, Labelling, and Storing Microscopical Preparations*, was read in his absence.

In the evening THE PRESIDENT delivered the *Annual Address*, choosing as his theme the

VERIFICATION OF MICROSCOPIC OBSERVATION.

He dwelt upon the extensive application of the microscope for research in almost all sciences and its universal practical employment in numerous applied sciences. He insisted with great earnestness upon the necessity of increased accuracy in microscopic work, illustrating such model work by reference to Tyndall's researches upon spontaneous generation, which comprised over eleven thousand single experiments. The means he suggested for the verification of work were: the repetition of observations, including demonstrations at societies; the use of the camera lucida, and especially of micro-photography; a judicious application of the most varied media and reagents based on all recent researches in chemistry and physics; and the employment of improved lenses and accessory apparatus. All these suggestions were happily illustrated by well-chosen references to appropriate instances.

WEDNESDAY, AUGUST 9TH, SECOND DAY.

PROF. BURRILL, of Champaign, Illinois, spoke on *Preparing and Mounting Bacteria*, giving principally his own experience in staining dried films with aniline colors and the various details to keep the permanent specimens in good order.

Dr. Detmers, of Champaign, made some extemporary remarks on *Pathogenic Bacteria*. The points of special interest were that he had traced Texas fever in cattle to the existence of bacteria in the blood, and that he considered micrococci not a complete form, but merely one of the stages in the cycle of development of certain micro-organisms.

Dr. George E. Fell, of Buffalo, spoke of the

CLINICAL ADVANTAGES OF OZONE AND ITS EFFECTS ON MICRO-ORGANISMS.

He referred at length to the observations of Dr. F. W. Bartlett, of Buffalo, who had used ozone clinically for many years by placing ozone generators in sick rooms in zymotic diseases. He claims to have observed in many cases a mitigation in the course of the diseases, as well as a checking of the spread of the contagious affection to other members of the families. At Dr. Bartlett's request, Dr. Fell had made some incomplete observations on the effect of ozone upon the growth of bacteria. For this purpose, he placed nourishing infusions partly into the ordinary air, partly into chambers in which the presence of phosphorus generated ozone, with the result that, in some instances, ozone hindered bacterial development, but not in all.

In the following discussion, various members gave their experience in attempting to limit the spread of contagious diseases by the use of volatile antiseptics other than ozone. No precise statements, however, were brought forth.

Prof. Burrill pointed out the difficulties met with in the destruction of bacteria by antiseptics in solution, and suggested how unsatisfactory any attempt must be to annihilate bacteria or disease germs in the air; for all disinfectants proved harmful to animals in much less concentration than is requisite to affect the bacteria in the air.

Dr. Gradle endorsed these remarks and illustrated the difficulties of disinfection by referring to the care necessary to render a Lister dressing successful, stating that notwithstanding the abundant presence of carbolic acid, any slight negligence in the application of the dressing may open the way for infection of or through the wound. He suggested that the want of uniformity in the results of Dr. Fell might be due to the presence of different species of bacteria in different instances; for other observers had found difference in the resisting power of different species of micro-organisms to ozone.

Dr. Blackham presented the report of the committe on *Eye-pieces*.

In the afternoon, Dr. Blackham moved to reciprocate the courtesy of the Royal Microscopical Society, by electing its President an *ex-officio* member of this Society, which was adopted.

Prof. Rogers, of Harvard University, read an elaborate paper upon *A Critical Study of the Action of a Diamond in Ruling Lines upon Glass*, which was followed by **Prof. Chester's** (Hamilton College) paper on *Dry Mounting*.

In the evening, **Prof. Walmsley**, of Philadelphia, described and illustrated the details of *Photo-micrography*, and **Prof. Kellicott**, of Buffalo, described *Some Infusoria found on Cray Fish*.

Thursday, August 9th, Third Day.

Dr. A. M. Bleile, of Columbus, read a paper on

THE EFFECTS OF THE DIVISION OF THE VAGI ON THE MUSCLES OF THE HEART,

of which the following are the conclusions:

1. The fibres of the pigeon are more delicate and more friable than in the rabbit.
2. In young pigeons the cross-striation of the muscular fibres of the heart is indicated by the fine granules which might be mistaken for beginning degeneration.
3. Even in the adult pigeon granular fibres are occasionally found by the side of well-marked striated ones, the former being perceptibly narrower. Possibly the granular fibres are still embryonic and destined to replace the older ones as needed.
4. Recently Prof. Rincus has pointed out that the frog's heart has two sets of muscles—the outer one termed the mouth, and the other forming, by its arrangement into trabeculæ, a system of lacunæ in which the blood circulates. In our pigeon-heart preparations, blood-corpuscles seem to lie in interstices, possibly corresponding to the lucunæ of the frog's heart, and these corpuscles when altered by reagents might be mistaken for larger fat-granules.
5. After division of one vagus only, there follows in the heart muscle of the pigeon a fatty degeneration, about equally marked on both sides of the heart, and more plain the longer the animal has been kept alive after vagotomy.
6. After double vagotomy, the degeneration is better marked—*i. e.*, the fat-granules are large, and appear sooner than after one-sided vagotomy. Hence, we conclude that the vagus in the pigeon, as in the rabbit, carries trophic cardiac fibres—no other explanation accounting for the changes found—and that the influences descending by one nerve are sufficient to somewhat retard the degeneration on both sides, which would follow a double vision.

Prof. Updegraff, of Elmira, presented a paper defining *Some Hitherto Undescribed Animalculæ—Perekella-Annelida-Brachionus*, which was dissented from by Prof. Kellicott, who considered these forms but larval stages of other animals.

Dr. Christopher Johnston, of Baltimore, made some remarks upon *A New Method of Polarizing Chemical Crystals*.

The sympathy of the Society was extended to Dr. R. H. Ward, of Troy, the first President of the Society, who has for a long time been hopelessly confined to his home with sickness.

Prof. Rogers then presented an elaborate report of his measurements of the corrections of *A Standard Centimetre*, for which faithful work the thanks of the Society were extended to him. The standard of Prof. Rogers was accepted by the Society.

Prof. Blackhorn, of Dunkirk, presented a paper on *The Relation of Aperture to Amplification in the Selection of a Series of Microscopic Objectives*.

In the evening the Calumet Club held a brilliant and well-attended microscopic *conversazione* and reception in honor of the Society.

Friday, August 10th, Fourth Day.

After the transaction of private business, the following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Hon. J. D. Cox, of Cincinnati.

Vice-Presidents.—Prof. T. J. Burrill, of Champaign, Ill., and Prof. W. E. Rogers, of Harvard University.

Executive Committee.—Prof. A. H. Chester, of Clinton, N. Y.; Dr. H. A. Johnson, of Chicago; and Gen. Wm. Humphrey, of Jackson, Mich.

Dr. Belfield, of Chicago, showed some *Microphotographs of Lard*, pure and adulterated, to prove that the adulteration with tallow can be detected by the form of the crystals.

Dr. V. S. Clevenzger, of Chicago, read a paper on the *Structure of the Brain in Health and Disease*.

Dr. Thomas Taylor, of Washington, forwarded a paper on *Parasites in Fowls*, describing several varieties of mites found in the tissues of diseased animals.

Dr. M. L. Holbrook, of New York, presented a paper on the

TERMINATION OF THE NERVES IN THE KIDNEYS.

By staining sections of kidney with chloride of gold he traced an abundant network of non-medullated nerve-fibres around the vessels, and could in some instances follow the ultimate fibrillæ into the cement-substance between the endothelial cells.

After the presentation of some additional papers and short addresses by the retiring and incoming Presidents the Association adjourned.

NEWS ITEMS.

The Cholera in Egypt. — The mortality from cholera during the past week is undiminished. The disease has spread in Alexandria, and the mortality has decreased at Cairo.

The cholera mortality returns are as follows:

	Cairo.	Alexandria.	Total for Egypt.
August 7,	70	13	682
" 8,	78	12	627
" 9,	39	22	795
" 10,	37	22	926
" 11,	30	33	789
" 12,	11	21	407
" 13,	6	44	675

The Sanitary Commission has decided to remove the cordon around Alexandria.

Is it Cholera?—English doctors now at Alexandria, who have had experience in India in cholera, as well as the Indian doctors, are reported as saying, that the disease now prevailing in Egypt is of a distinctly different character from the Asiatic cholera. Dr. Abatti, the personal physician of the Khedive, who accompanied His Highness to Cairo, is also reported to have said that his observations there, coupled with his experience in 1865, lead him to the conclusion that the cholera is not of the Asiatic type.

Medical Notes of the Cholera Epidemic.—Dr. J. Mackie, Surgeon to the British Consulate at Alexandria, in his report of July 15th, to the British Foreign Office says: Since my report of the 9th instant [see The Medical News, August 4th, p. 137] there has been a notable decrease in the mortality from cholera in the two villages which have suffered most severely—Damietta and Mansurah. The virulence of the disease, however, seems to continue unmitigated, if I can rely on reports which reach me from intelligent correspondents. The Board of Health at Cairo can give no information, and I am obliged to glean my information from other sources. Reports have been sent to me from Damietta and Mansurah of cases of death in from two to three hours, in which there had been neither vomiting nor diarrhœa. This seems to have occurred so often, that many inhabitants of those villages do not believe it is cholera, but some new disease. I remember, in my own experience and practice here in the cholera of 1865, many such cases. Though the number of victims in the villages first attacked has diminished, and no very severe outbreak has shown itself in any of the other villages, yet, from slight outbreaks occurring here and there, the disease shows a great tendency to spread.

Up to the present, the route it has taken is along the Damietta branch of the Nile southward, in the direction of traffic and prevailing wind, the only deviation from this line of progress as yet being Port Said, Menzaleh, Chibin-el-Koum, and Alexandria, and at none of these places, except, perhaps, Menzaleh, have there been more than a few cases. If this steady, though slow, progress continues, it is likely to find its way along the Nile to Cairo. The cases which have occurred at such places as Chibin-el-Koum and Port Said, may be accounted for by persons escaping from the infected villages, but I have no authentic information.

A great many of the soldiers forming the *cordons sanitaires* have taken the disease, notwithstanding the care taken, and stringent orders issued by the English officers. A letter from Colonel Sartorius of the 12th instant states: "One man Damietta *cordon* taken ill to-day. One officer, eleven non-commissioned officers Mansurah *cordon*, taken ill to-day. Talka *cordon*, one soldier, one officer, and nine men Samanoud *cordon* taken ill to-day, and two men dead. Chibin-el-Koum *cordon*, four taken ill and two dead three days ago." A paragraph, presumably authentic, in the *Egyptian Gazette* of the 14th instant, states "that it was found necessary to change the position of the *cordon* at Samanoud. In doing so, it was necessary to cross a native graveyard, where victims to the prevailing disease had only recently been interred. During the one night that the sentinels remained in the cemetery, they caught the malady."

The disease has now been raging in Egypt for twenty-four days in as fatal a form as the cholera of 1865, judging from the published bulletins; and, with the exception of the few cases at Port Said, most, if not all, of which the sanitary physician declares occurred in refugees from Damietta. The route across Egypt, from Asia to Europe, has been free. The origin of the outbreak at Damietta remains as obscure as ever. The Sanitary Board of Cairo has now announced, almost officially, its belief that the disease has been imported from Bombay. Others also express the same belief, holding the opinion that cholera invariably spreads from India, while those who are not bound by opinion, and ask investigation and proof, are inclined to find in the unsanitary state of the country where the disease first broke out, sufficient to account for an outbreak without importation. If the substance or germ necessary for the production of cholera can be produced or evolved from decaying animal matter, a local origin can easily be found at Damietta. What constitutes cholera, even in India, the means by which it is propagated, are now generally understood; but there must be a first beginning. What is it? If it has had its first beginning in unsanitary India, why not in unsanitary Damietta, with a river flowing through it supplying it with water filled with rotting carcasses of animals which have died of cattle-plague, four hundred of which, according to authentic information, have been fished out and buried since the disease appeared. The soil around is also the best that could be for the propagation of cholera, being loosely alluvial and fecal, and the water often nearly stagnant from the tidelessness of the sea. Under such circumstances, cholera could dwell and thrive. The question still is, how could it originate? The study of this epidemic will be epidemiologically, commercially, and politically of most intense interest, and the investigators will have to be independent men, free from all political influence, if truth is to be arrived at.

The Egyptian medical and sanitary administration has been showing great activity lately, and sent doctors, medicines and disinfectants to the infected villages; but sending one or two young medical men with disinfectants to disinfect an Egyptian village and stop cholera is like pouring a bucketful of water in the sea to flood a stranded ship. However well the work may look when published in the *Moniteur*

Egyptian, it is nearly practically useless. To disinfect an Egyptian town means destroying and reconstructing it—it is impossible to cleanse and disinfect it. And, moreover, I will undertake to say that nine-tenths of the men sent to do the work do not themselves appreciate the meaning and use, and method of disinfection. Sanitary habits and practice which will stop the progress of a zymotic disease are yet foreign to the country and to the nature of the people. Dr. Chaffey Bey reports from Damietta that the measures ordered are not carried out. Benevolent societies have been formed, chiefly by Europeans, to send aid to stricken villages, and have sent at their expense several European doctors who expressed their readiness to go. Many European doctors, experienced in cholera and epidemics, would gladly go to help authorities by their advice, but the difficulty of returning to their work here in case of need, without undergoing a lengthened quarantine, prevents them.

It would seem as if the *cordons sanitaires* have retarded the progress of the disease, and they may retard it till the country is supplied with good water by the rising of the Nile; but there are many reasons why the *cordons sanitaires* cannot stop its progress; where a case, for instance, happens in a village at some distance from an infected place, the people, or some of them, immediately take flight for fear of being shut in, and have escaped long before a *cordon* can be formed. Several cases have come before me, where people have arrived ill of fright, from villages where, perhaps, during the night, some one had died suddenly, and they had fled in terror from supposed cholera and to escape the *cordon sanitaire*. To make it more effective, it would be necessary to surround not only the villages infected, but the whole district.

Under date of July 17th, Dr. Mackie writes that the tendency of the disease to spread, notwithstanding *cordons sanitaires*, is very marked, and I am afraid there is now little hope of saving the country. It has now left the banks of the river and spread more in the direction of the chief line of railway. The *cordons sanitaires* are on a severe trial, and the result will prove whether they have been of any real use. If they prove to be a failure, it is to be hoped that they have had their last trial, here or elsewhere, as they are the cause of great panic and much hardship, which one would not desire to see inflicted if no good result is to be obtained.

Judging the rate of progress of this outbreak by that of 1865, when nothing was done, and the development and spread were so rapid that nothing could be done, it would seem as if the *cordons* have retarded the progress; but that they will stem the tide completely, I have no hope. The fatal nature of the malady is still its marked feature; in that it resembles real Asiatic cholera.—*British Med. Journal*, July 28, 1883.

French Comments on the Cholera in Egypt.—M. Fauvel, at the meeting of the Academie de Médicine of July 24th, fully discussed the present danger of an invasion of cholera. This danger, he said, is in inverse ratio to the distance from the infected point. At present Syria is in most danger on account of its proximity to Egypt, though the invasion of that country does not necessarily compromise Europe. But if Constantinople is attacked, the outlook for Europe is serious; for it will be in vain for Russia, Bulgaria, and Roumania to quarantine. Greece will, in all probability, be able to protect itself, isolated as it is in a great measure. Trieste is a dangerous point for Europe. The Italian Government has made every effort to prevent the importation of the disease, but these efforts are rendered partially futile by insufficient means of action, and the want of energy in the government agents. As to the maritime coast of France, the strict precautionary measures taken since the first outbreak of the disease rather preclude the idea of an attack from that quarter. But there are no measures for preventing an invasion from other European countries should they be attacked. The great question of the moment is, therefore, to prevent the invasion of any part of Europe.

The fact that England is in constant relation with the infected countries should not be lost sight of. The length of the voyage from Port Said to England is not less than fourteen days by steamer: but after fourteen days, if no cholera breaks out on board the vessel, there is no chance that it will be communicated by the passengers, and the English Government will cause all suspected cargoes to be disinfected. The history of cholera in England shows, that whenever that country has suffered from an epidemic, the disease was scourging the northern ports of Europe, and that England's invasion was from that source. Taking these things into consideration, we may affirm that Europe has a good chance of escaping an epidemic. One of the rules of cholera is that the more violent the epidemic, and the more rapid its extension, the shorter is its course and the sooner its extinction; and it is highly probable that the present epidemic will have died out in Egypt in five weeks more. The cholera in Egypt was an importation from India, and is the consequence of the suppression of proper measures for protecting the country, and at England's door lies the responsibility of its importation.

Sanitary Precautions in Turkey.—The Sanitary Council has ordered that vessels arriving from Smyrna be subjected to observation for twenty-four hours in the Dardanelles. This order is due to the fact that a French man-of-war from Port Said disregarded the quarantine regulations at Smyrna and communicated with the town.

British Precautions against Cholera.—The precautionary measures taken by England to prevent the introduction of cholera into her home ports are herewith presented as being of general interest to sanitarians in this country.

The Local Government Board has issued the following rules and regulations, to be enforced and executed by the Port Sanitary Authority for the Port of London:

For the purposes of this Order every ship shall be deemed infected with cholera in which there is or has been during the voyage, or during the stay of such ship in a port in the course of such voyage, any case of cholera.

I.—Regulations as to Detention by Officers of Customs.

Art. 2. If any Officer of Customs, on the arrival of any ship in the Port of London, ascertain from the master of such ship or otherwise, or have reason to suspect that the ship is infected with cholera, he shall detain such ship, and order the Master forthwith to moor or anchor the same in such position as such Officer of Customs shall direct; and thereupon the Master shall forthwith moor or anchor the ship accordingly.

Art. 3. While such ship shall be so detained no person shall leave the same.

Art. 4. The Officer of Customs detaining any ship as aforesaid shall forthwith give notice thereof, and of the cause of such detention, to the Sanitary Authority.

Art. 5. Such detention by the Officer of Customs shall cease as soon as the ship shall have been duly visited and examined by the Medical Officer of Health, or, if the ship shall, upon such examination, be found to be infected with cholera, as soon as the same shall be moored or anchored in pursuance of Art. 10 of this Order. *Provided*, That if the examination be not commenced within twelve hours after notice given as aforesaid, the ship shall, on the expiration of the said twelve hours, be released from detention.

II.—Regulations as to Sanitary Authorities.

Art. 6. The Sanitary Authority shall, as speedily as practicable, with the approval of the Chief Officer of Customs of the port, fix some place within the jurisdiction of the Sanitary Authority where any ship may be moored or anchored for the purpose of Art. 10; and shall make provision for the reception of cholera patients and persons suffering from illness removed under Articles 13 and 14.

Art. 7. The Sanitary Authority, upon notice being given to them by an Officer of Customs under this Order, shall forthwith cause the ship, in regard to which such notice shall have been given, to be visited and examined by the Medical Officer of Health, for the purpose of ascertaining whether she is infected with cholera.

Art. 8. The Medical Officer of Health, if he have reason to believe that any ship within the jurisdiction of the Sanitary Authority, whether examined by the Officer of Customs or not, is infected with cholera, shall, or if she have come from a place infected with cholera, may visit and examine such ship for the purpose of ascertaining whether she is so infected; and the master of such ship shall permit the same to be so visited and examined.

Art. 9. If the Medical Officer of Health on making such examination as aforesaid (whether under Art. 7 or 8) shall be of opinion that the ship is infected, he shall give a certificate in duplicate, and shall deliver one copy to the Master and retain the other, or transmit it to the Sanitary Authority:

Art. 10. The Master of every ship so certified to be infected with cholera shall thereupon moor or anchor her at the place fixed for that purpose under Art. 6, and she shall remain there until the requirements of this order have been duly fulfilled.

Art. 11. No person shall leave such ship until the examination hereinafter mentioned shall have been made.

Art. 12. The Medical Officer of Health shall, as soon as possible after any such ship has been certified to be infected with cholera, examine all persons on board of the same, and all persons who shall not be certified by him, as hereafter mentioned, shall be permitted to land immediately on their giving their names and the places of their destinations.

Art. 13. Every person certified by the Medical Officer of Health to be suffering from cholera shall be dealt with under any regulations that may have been made by the Sanitary Authority under Sec. 29 of the Sanitary Act, 1866; or, where no such regulations shall have been made, shall be removed, if the condition of the patient admit of it, to some hospital or place previously appointed for that purpose by the said Sanitary Authority; and no person so removed shall leave such hospital or place until the Medical Officer of Health shall have certified that such person is free from the said disease. If any person suffering from cholera cannot be removed from the ship, she shall remain subject, for the purpose of this Order, to the control of the Medical Officer of Health; and the infected person shall not be removed from or leave the ship, except with the consent, in writing, of the Medical Officer of Health.

Art. 14. Any person certified by the Medical Officer of Health to be suffering from any illness which such officer suspects may prove to be cholera, may either be detained on board the ship for any period not exceeding two days, or taken to some hospital or other place previously appointed by the Sanitary Authority, and detained there for a like period, in order that it may be ascertained whether the illness is or is not cholera. Any such person who, while so detained shall be certified by the Medical Officer of Health to be suffering from cholera, shall be dealt with as provided by Art. 13 of this Order.

Art. 15. The Medical Officer of Health shall in the case of every ship certified to be infected, give directions, and take such steps as may appear to him to be necessary for preventing the spread of infection, and the master of said ship shall forthwith carry into execution such directions as shall be so given to him.

Art. 16. In the event of any death from cholera taking place on board of such ship while so detained, the Master shall, as directed by the Sanitary Authority or the Medical Officer of Health, either cause the dead body to be taken out to sea and committed to the deep, properly loaded to prevent its rising, or shall deliver it into the charge of said authority for interment; and the Authority shall thereupon have the same interred.

Art. 17. The Master shall cause any articles that may have been soiled with cholera discharges to be destroyed, and the clothing and bedding and other articles of personal use likely to retain infection which have been used by any person who may have suffered from cholera on board such ship, or who, having left such ship, shall have suffered from cholera during the stay of such ship in any port, to be disinfected, or (if necessary) destroyed; and if the Master shall have neglected to do so before the ship arrives in port, he shall forthwith, or upon the direction of the Sanitary Authority or the Medical Officer of Health, cause the same to be disinfected or destroyed, as the case may require; and if the said Master neglects to comply with such direction within a reasonable time, the Authority shall cause the same to be carried into execution.

Art. 18. The Master shall cause the ship to be disinfected, and every article therein, other than those last described, which may probably be infected with cholera, to be disinfected or destroyed, according to the direction of the Medical Officer of Health.

DISINFECTION OF THE MAILS AT MARSEILLES.—A laboratory has been fitted up at Marseilles for the purpose of disinfecting the mails. It consists of a closet in which is a large table for receiving the contents of the mail sacks. The postal agents of the ship under observation carry the mail matter and sacks, previously unfastened, to the closet; they then retire to the ship or lazaretto. After having hermetically closed all the openings in the chamber, carbolized or chlorinated vapor is thrown in. After this the postal clerks of the city bring their mail, put it into the disinfected sacks, which are left for the postal clerks of the ship, and they carry away with them the disinfected mail. There is no communication between the two sets of clerks. Before being fumigated, the wrappers and envelopes of all the mail matter are cut through.

THE MEDICAL NEWS' Indian mail, just received, bears emphatic evidence of this antiseptic treatment, having been punctured through and through, in several places, by a broad, flat, and sharp instrument, and upon opening, it smelled strongly of chlorine.

CHOLERA HOSPITAL FOR PARIS.—The Director of Public Charities in Paris has asked the Municipal Council to grant a credit of 1,500,000 francs to be used in building a provisional hospital of 600 beds, in view of an attack of cholera. The Commission proposes—1. To give a sum of 400,000 francs. 2. To devote this sum to the construction of barracks, to contain 200 beds, with the necessary attendants and facilities for treatment.

CHOLERA PRECAUTIONS IN SPAIN AND PORTUGAL.—The Department of State has been informed by the United States Consul General at Lisbon, that sanitary measures have been taken by the Portuguese Government against the introduction of cholera. By a ministerial decree the Egyptian ports of the Mediterranean were declared infected by cholera, and all the Red Sea ports were declared suspected. The Spanish Government has imposed like vigorous measures upon vessels arriving from the English ports, and a portion of the Madrid press has advised that until like restrictions are imposed in Portuguese ports upon such vessels, an embargo be laid upon all persons entering Spain by land from Portugal. It is said that concert of action is contemplated by certain of the European powers as regards the continental ports of Central Europe, and that stringent measures are under consideration to restrict intercourse with infected ports.

CHOLERA PRECAUTIONS IN BERLIN.—The health officer of Berlin has issued the following instructions regarding the precautions to be taken to prevent the introduction of cholera into Germany:

The disinfectants used in ships must be; (1) a solution of pure carbolic acid in water (1–18). 2. Corrosive sublimate solution must be used for disinfecting the holds of ships and their contents. 3. Where these disinfectants cannot be conveniently used, steam, at a temperature of 280° Fah., must be employed for one or two hours. The different apartments of the ships, especially the cabins, berths, and the spaces between decks must be disinfected with carbolic acid solution. The decks, walls, and floors must be washed with rags previously soaked in the carbolic acid solution. The sick-rooms, and all vessels and utensils must be frequently washed and disinfected with this solution. Clothing must be washed in a disinfecting solution and then subjected to steam disinfection. 4. Where it is necessary to disinfect a person, he must be thoroughly washed with green soap, and must afterward be bathed. 3. Bodies of persons supposed to have died of cholera on board ship must be wrapped in cloths as soon as possible, and soaked in carbolic acid solution.

The disinfection of the holds of ships and their contents is to be carried out, with solution of corrosive sublimate, in the following manner: According to the quantity of bilgewater, one and a half to two and a half pounds of corrosive sublimate must be completely dissolved in from ten to twenty quarts of water. (For every thousand quarts of bilgewater two and one-half pounds of sublimate must be used.) Then, by means of a pump and a pipe running above deck the water must be pumped from the after part through the pipe to the forward part of the hold. It is of course understood that care must be taken, in case the hold is not connected throughout, that this washing must extend to the separate partitions of the bulk-heads, and a complete circulation of the bilgewater carried on. The sublimate solution must then be poured into the forward part of the hold and the pumping again carried out. On account of the poisonous nature of corrosive sublimate, all vessels containing it or its solution must be properly labelled, and after being used must be locked up. To know whether the disinfection has been properly carried out, and the water thoroughly impregnated with the solution, a strip of copper sheathing cleaned with emory-paper must be let down half-way into the water. If the disinfection is sufficient, there will form, at the expiration of about two minutes, a distinct gray coating upon the part of the copper strip which was immersed. If this coating does not form at the end of two minutes, the disinfecting solution is not sufficiently strong and must be strengthened and the pump-work gone over again.

After the bilgewater has been treated in the above manner with the sublimate solution, it must be left in the hold for twenty-four hours; at the expiration of this time the contents of the hold must be pumped out and an equal quantity of sea-water pumped in. In cases in which it is suspected that some of the old water still remains, this must be repeated at least three times.—*Berliner klin. Wochensch.*, No. 31, 1883.

GERMAN INVESTIGATION INTO CHOLERA.—The German government will send a scientific expedition to Egypt this week to examine into the origin, nature, and cause of the cholera now prevailing there, and to ascertain the best measures to prevent the spread of the disease.

QUARANTINE AT SAN FRANCISCO.—Fearing the introduction of cholera from China and Japan, the Board of Health has adopted a resolution that all Asiatic ports be declared infected, and that all vessels arriving be quarantined until the fullest examination be made.

YELLOW FEVER IN HAVANA.—There were twenty-nine deaths from yellow fever in Havana, for the week ending August 11th.

SMALLPOX IN NEW ORLEANS.—The mortality from smallpox for the week ending August 4th was thirteen, against twenty-one for the preceding week.

SMALLPOX IN MINNESOTA.—The smallpox is reported to be making terrible ravages among the Indians of Itaska county, Minnesota. In two small towns eighty-five deaths have been reported.

AMERICAN DERMATOLOGICAL ASSOCIATION.—The seventh annual meeting will be held at the Sagamore House, Green Island, Lake George, on Wednesday, Thursday, and Friday, August 29th, 30th, and 31st. Papers will be read by the following gentlemen: Dr. Piffard, Treatment of Acne; Dr. Hyde, A Study of the Coincidence of Syphilitic and Non-Syphilitic Affections of the Skin; Dr. Graham, General Exfoliative Dermatitis; Dr. Stelwagon, Impetigo Contagiosa; Dr. Robinson, Alopecia Areata; Dr. Duhring, 1. On the Value of a Lotion of Sulphide of Zinc in the Treatment of Lupus Erythematosus, 2. Report of a Case of Ainhum with Microscopic Examination; Dr. Atkinson A Case of Multiple Cachectic Ulceration; Dr. Sherwell, 1. Pseudo-Psoriasis of the Palm, 2. Malignant Papillary Dermatitis; Dr. Bulkley, 1. A Hitherto Undescribed Vegetable Parasite Found on the Human Skin; 2. A Clinical and Experimental Study on Pruritis; Dr. Van Harlingen, Experiments in the Use of Naphthol; Dr. Fox, A Trip to Tracadie.

THIRD INTERNATIONAL OTOLOGICAL CONGRESS.—The Committee of Organization for the Third International Otological Congress—Dr. Burchhardt-Merian (Bâsle), president, A. Hartmann (Berlin), L. Löwenberg and Ménière (Paris)—at a meeting on March 18th, decided to abide by the decision of the Second Congress to hold the session of the Third in Bâsle, Switzerland, the first week in September, 1883. The committee enlarged their number by the addition, among others, of Drs. St. John Roosa of New York, and Blake of Boston.

A SANITARY CONVENTION will be held at Muskegon, Michigan, on August 23d and 24th, under the auspices of the State Board of Health.

There will be sessions the first day at 2 P.M. and 8 P.M.; on the second day at 9 A.M., 2 P.M., and 8 P.M. At each session there will be addresses or papers on subjects of general interest pertaining to public health, each paper to be followed by a discussion of the subject treated.

The objects of the Convention are the presentation of facts, the comparison of views, and the discussion of methods relating to the prevention of sickness.

Among the subjects of general interest which it is expected will be presented and discussed are the following:

Communicable diseases—scarlet fever, diphtheria, and smallpox.

Ventilation of residences and public buildings.

Food, and the sanitary regulation of markets.

Instruction in the public schools on the effects of alcohol and narcotics.

Adulterations and nostrums.

The disposal of refuse organic matter.

The International Medical Congress, Copenhagen, 1884.—The eighth International Medical Congress will be held in Copenhagen from August 10 to 16, 1884. The General Organizing Committee, formed for the preparatory work, is composed of the following members, living either in or near Copenhagen: *President:* Prof. Dr. P. L. Panum. *Secretary-General:* Prof. C. Lange. *Secretaries;* Dr. O. Bloch, Dr. C. J. Salomonsen, and Surgeon-General Joh. Möller. *Honorary Treasurer:* Prof. Dr. E. Hansen Grut, besides the Chairmen of the Sections, viz.: *Anatomy:* Prof. Chievitz. *Physiology:* Prof. Dr. P. L. Panum. *General Pathology and Pathological Anatomy:* Prof. Dr. C. Reisz. *Medicine:* Prof. F. Trier. *Surgery:* Prof. Dr. Holmer. *Hygiene and State Medicine:* Dr. E. Hornemann. *Military Surgery and Medicine:* Director-General of the Medical Department of the Army, Salomon. *Mental and Nervous Diseases:* Prof. Dr. Steenberg. *Obstetric Medicine and Surgery, and Gynæcology:* Prof. Dr. Stadfeldt aud Prof. Dr. Howitz. *Diseases of Children:* Prof. Dr. Hirschsprung. *Ophthalmology:* Prof. Dr. E. Hansen Grut. *Diseases of the Skin and Syphilis:* Prof. Dr. Haslund. *Diseases of the Ear and Throat:* Dr. W. Meyer.

In order that the meeting of so many distinguished medical men, who, it is hoped, will attend on this occasion, may be as advantageous as possible, the Organizing Committee, following the example of the later Congresses, will communicate with distinguished men of different branches and of different countries, in order to prepare a programme. "This programme, as well as the rules, will be forwarded to those of our colleagues who we suppose take an interest in the work of the Congress, and who might be inclined to participate in it. In order that the programme may be ready as soon as possible, we shall be pleased if communications, referring to the work of the Congress, are sent to the Secretary-General before October 1 next, so that it may be possible for us to have regard to them in arranging the definite programme. The programme and rules will be forwarded, as soon as possible, to everyone qualified to participate in the Cougress, who within the limited time has announced to the Secretary-General his interest in the Congress, and his intention of participating in it; and, if possible, which section he intends chiefly joining."

Honors to Medical Men.—The Queen has conferred the honor of baronetcies on Mr. Prescott Hewett and Dr. Andrew Clark, and a knighthood on Mr. George Porter, of Dublin. The profession in Ireland remonstrated that a Surgeon of the Queen, in Ireland, should not have been the recipient of an hereditary title. Dr. Banks to whom a knighthood was also offered, in view of this expression of opinion of his colleagues in London, has felt it inconsistent with his professional duty to accept this mark of royal favor.

Health in Michigan.—Reports to the State Board of Health for the week ending August 4, 1883, indicate that inflammation of the bowels, cholera infantum, remittent fever, typho-malarial fever, and whooping-cough have increased, and that diarrhœa has decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending August 4, and since, at sixteen places; scarlet fever at twelve places; and measles at eleven places.

Compared with the average for the month of July in the preceding six years, neuralgia and bronchitis were considerably more prevalent, measles, rheumatism, and tonsillitis were more prevalent, and membranous croup, whooping-cough, and remittent fever were less prevalent during the month of July, 1883.

Obituary Record.—At Albany on August 13th, in the fiftieth year of his age, Jacob S. Mosher, M.D., Professor of Medicine in the Albany Medical College.

Dr. Mosher was born in Albany County on March 19, 1834. He entered Rutgers College in 1853, and in 1863 he received the degree of M.D. from the Albany Medical College. He at once tendered his services to the Government, and until the close of the war he served with the Army of the Potomac, and in the Washington Hospitals. He was Surgeon-General of the State of New York under Governors Hoffman and Dix, and from 1870 to 1876 he was Deputy Health Officer of the port of New York. At the time of his death he was a member of the Albany Board of Health, a Professor in the Albany Medical College, Dean of the Faculty of the College of Pharmacy, President of the Alumni of the Albany Medical College, and Physician to the Albany Hospital.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 6 TO AUGUST 13, 1883.

McParlin, Thomas A., *Lieutenant-Colonel and Assistant Medical Purveyor.*—Relieved from duty in charge of Purveying Depot in San Francisco, California, to take effect September 1, 1883, and will then proceed to New York City, and relieve Assistant Medical Purveyor Ebenzer Swift of the charge of the Purveying Depot in that city. Assistant Medical Purveyor McParlin will transfer all funds and public property in his possession to Medical Storekeeper Henry Johnson, who, until further orders, will perform the duties of Acting Assistant Medical Purveyor at the Purveying Depot in San Francisco.—*Par. 5, S. O. 183, A. G. O., August* 9, 1883.

Woodward, Joseph J., *Major and Surgeon.*—Leave of absence granted, on account of sickness, by S. O. 34, extended six months.—*S. O. 179, A. G. O., August* 4. 1883.

Byrne, Charles B., *Captain and Assistant Surgeon.*—Relieved from duty at Fort Craig, N. M., and assigned to duty at Fort Lewis, Colorado.—*Par. 3, S. O. 161, Department of the Missouri, August* 6, 1883.

Lauderdale, John V., *Captain and Assistant Surgeon.*—Granted leave of absence for two months, to take effect on or about the 15th instant.—*Par. 2, S. O. 90, Department of the Missouri, August* 6, 1883.

Banister, John M., *First Lieutenant and Assistant Surgeon.*—Relieved from duty in the Department of the Missouri, and assigned to duty in the Department of the East.—*Par. 5, S. O. 183, A. G. O., August* 9, 1883.

Carter, William F., *First Lieutenant and Assistant Surgeon.*—Relieved from duty in the Department of Texas, and assigned to duty in the Department of the East.—*Par. 5, S. O. 183, A. G. O., August* 9, 1883.

Kane, John J., *First Lieutenant and Assistant Surgeon.*—Relieved from duty in the Department of the Missouri, and assigned to duty in the Department of the East.—*Par. 5, S, O. 183, A. G. O., August* 9, 1883.

Owen, W. O., Jr., *First Lieutenant and Assistant Surgeon.*—To proceed from Vancouver Barracks to Fort Walla Walla, W. T., and report to the commanding officer of the latter post for temporary duty.—*S. O. 101, Department of the Columbia, July* 27, 1883.

ORIGINAL LECTURES.

PREATAXIC TABES DORSALIS.

A Clinical Lecture delivered during the summer session of the McGill Medical Faculty.

BY WILLIAM OSLER, M.D., F.R.C.P. LOND.,
PROFESSOR OF THE INSTITUTES OF MEDICINE, MCGILL COLLEGE, MONTREAL.

GENTLEMEN: In locomotor ataxia we may, for clinical convenience, recognize three stages, the *preataxic*, in which, without any incoördination, there are certain other well-defined and characteristic symptoms; *the ataxic*, in which the disordered muscular movements predominate; and a final *pseudo-paralytic* stage, in which the patient is a helpless cripple. The man before you is an interesting illustration of the early, or preataxic stage. You see, as he walks around the arena, that the gait is normal, and you certainly would not suppose from his appearance that he was afflicted with this disease. From the fact that locomotor ataxia may exist for years without *ataxia*, the name tabes dorsalis, given by Romberg, is preferable, or posterior spinal sclerosis, which indicates the location and nature of the lesion. When we consider that about fifty per cent. of tabetic patients are not ataxic[1] the name in common use is misleading, and gives undue prominence to a symptom which is often absent.

The clinical record of this patient is as follows: Samuel S., of Sherbrooke, Que., aged 43, Canadian, a cabinetmaker by trade, but for some years (12) past a millwright, came to the hospital to be treated for failure of eyesight. Nothing special in the family history. Has been married nineteen years; two children living, three dead; one, a year old, had a rash on the body, the other two were still-born. Had gonorrhœa; can get no history of chancre. Formerly took spirits freely, but has been temperate for some years. Has used tobacco to excess, also opium. In his occupation as millwright has been much exposed to wet and cold, particularly when working in the flumes, and on several occasions has been for hours in ice-cold water. For nearly four years he has had what he calls rheumatic pains in the legs, at irregular intervals; sometimes six months would elapse, and at others two or three attacks would occur in a couple of weeks. He describes the pains as intense, coming on with great rapidity, localized often in spots not more than an inch or two in extent, which are acutely sensitive when they are present; duration brief, two or three seconds, and then they pass away as quick as they came, to return again in a few minutes. Sometimes they have been so bad that he has not slept; in his own words, "they would just give me breathing spells, and then I had to clinch my teeth to bear the next pain." No tingling or pins and needles. For about a year has noticed that the eyesight was failing; may have been present for a longer time, but he was not conscious of it.

Examination: Patient is a slight, dark man, fairly nourished. Gait is unaffected. Muscles moderately developed. Sensation in legs good; not retarded. Pupils are contracted, round, measure 3.5 mm. They do not react to light (reflex immobility, reflex iridoplegia). Act during accommodation and in associated movements when eyes move upward and inward. Dr. Buller tested the vision, and reports $\frac{6}{100}$ with right eye and $\frac{22}{100}$ with left eye. Considerable limitation of field of vision in upper and outer parts. Optic nerves bluish-white in color; margins well defined; all the minute vessels of the disk are gone, only the larger trunks remain, and they, too, are diminished in size. Color-perception for red and yellow good; he thought the green was dark-brown, almost black. The patellar tendon-reflex is absent. Plantar, cremasteric, and abdominal reflexes are present.

The eye symptoms, lightning pains, and absence of knee-jerk, are the chief features presented by this case, and together they are amply sufficient to establish the diagnosis of tabes dorsalis. Let us consider these symptoms a little more closely, and, first, the ocular phenomena, which are among the earliest and most remarkable nerve disturbances in the disease, and of great diagnostic importance. When I place the patient before the window, shade his eyes with my hand, and then suddenly expose them to the bright light, no change takes place in the diameter of the pupils. Tested with a stronger light, the same peculiarity is noted; the pupils are immobile and do not react to the stimulus. If now, after looking at my fingers at eighteen inches he then directs his vision into the distance, the pupils dilate with the relaxation of accommodation, and contract again when he looks at a near object. While not responding to the stimulus of light, they are active during accommodation. This reflex immobility of the pupil, first described by Dr. Argyl Robertson, and sometimes called after him, is present in a large proportion of cases of tabes. In 84 cases of Prof. Erb it was noted absolutely in 59, and diminished in 12. Of these 71 cases, 43 were in the preataxic stage of the disease. In Gower's address, just to hand, on eye symptoms in spinal disease, the light reflex is stated to have been lost in 48 out of 72 cases. Usually the reflex immobility is associated with myosis, which exists in this man in a moderate degree. The only other affection in which this sign has been specially noted is progressive paresis of the insane. Not only is the power of reflex contraction of the pupils lost, but reflex dilatation may also be suspended. If you stimulate strongly the skin of a healthy person, a slow reflex dilatation of the pupils takes place, but in the majority of cases of tabes this does not occur. We could not get this reflex on strong galvanic stimulation of the skin of the neck and shoulder of this man. The precise locality of the lesion which causes these early pupil symptoms is unknown, but if you consult the diagram of the pupil centres, which you have in your physiology notes of last winter, you will see that, as Erb says, the local degeneration causing the loss of light reflex must be somewhere in the pathway between the centres of the optic and the third nerves.

The chief complaint of this patient is a steadily advancing loss of sight, which ophthalmoscopic examination shows to be due to atrophy of the optic nerve. Many of you have had an opportunity of examining the disks in the ophthalmoscope room, and studying the characters of the sclerotic atrophy—the blue-gray color, the flatness of the disks, the absence of small vessels, and their sharp distinct outlines. With no other spinal affection is atrophy of the optic nerves so frequently associated. It usually begins early, before the second stage of the disease is reached, and the patient may be quite blind by the time the ataxia develops, or, indeed, before there is a suspicion of tabes. The atrophy is progressive, and ultimately, though it may be after the lapse of months or even years, total blindness results.

---

[1] Erb, in eighty-four cases, mentions that forty-three were in the initial stage and presented no ataxia.

Color-perception is often disturbed; most frequently patients lose the power of distinguishing red and green, while that for yellow and blue may be retained. This man says that green appears to him dark-brown or almost black. His perception of red, yellow, or blue is good. There are other eye symptoms, not present in this instance, which may puzzle you not a little, if unaware of their connection with tabes. I refer to the local palsies of the external eye muscles, and the production of squint, double vision, and ptosis. These, too, are often preataxic symptoms and are quite as common as those which we have considered. Double vision, with or without positive squint, is often a most troublesome feature, and the patient may be for months under the care of an oculist, or, indeed, have an operation performed for strabismus. Some years ago, I knew a gentleman who had intractable ptosis and squint without any other special symptoms. He has since become ataxic. I have at present under observation a gentleman who had external strabismus and double vision for six or seven months, and now has severe pains, bladder trouble, and absence of the patellar reflex. In adult men, the occurrence of ptosis, squint, or double vision, should suggest to you the possibility of early tabes and the necessity of examining for other signs.

Besides the failure of vision, the patient has but one complaint—the terrible pains which have attacked him at times during the past four years. The account which I read to you, is a typical description of the so-called lightning or electric pains of tabes. They are usually mistaken for rheumatic pains, and affect chiefly the lower extremities, sometimes the back and sides, rarely the arms. They vary greatly in intensity and in the frequency of their occurrence; weeks or months may elapse between attacks. The suddenness of their onset, the rapid darting or flashing character, is well expressed in the terms electric, fulgurating, or lightning. They fly about from place to place, and when a bad bout comes the patient may cry out with each pain, and they may recur so rapidly that, as our patient says, there are only breathing spells between them and just time to clinch the teeth to bear the next stab. The skin over the site of the pain may be intensely sensitive—hyperæsthetic. Occasionally the pains are dull, heavy, and dragging, not sharp and stabbing; this, however, is quite exceptional. Very few, not five per cent., of ataxic patients escape these torments. One other important symptom is presented by this man; when I strike the patellar tendon of the crossed leg with the rim of the stethoscope, there is no response in muscular contraction of the quadriceps extensor, and the leg is not jerked up as in health. The knee-jerk or patellar tendon-reflex is absent, and since Prof. Westphal called attention to this sign, it has come to be regarded as of great diagnostic value in tabes. Exceptionally, the knee-jerk is absent in persons in whom there can be no suspicion of posterior spinal sclerosis; but absence of it in conjunction with lightning pains or any of the ocular phenomena, may be regarded as proof positive of the existence of the disease. Lest you may think that rather a strong statement, let me read you a paragraph from a lecture by Dr. Buzzard, whose work on *Diseases of the Nervous System* I would specially commend to you as embodying the rich clinical experience of an unusually acute observer. He says, "It is of much importance to remember that the two symptoms—on the subjective side, pains of the character described, and, on the objective side, absence of the patellar tendon-reflex (with a fairly normal condition of the quadriceps extensor muscle)—are the most constant, as they are probably the earliest of all. My belief is that if we meet a patient who exhibits them both, we do not need the presence of any other in order to form a diagnosis of tabes dorsalis." The patellar tendon-reflex is absent in about ninety-six per cent. of all cases.

Among other symptoms which may be present in the first stage are localized regions of anæsthesia, numbness, pins and needles, but more common with pronounced ataxia; attacks of obstinate vomiting occurring without obvious cause, the *crises gastriques* of Charcot, and vesical and rectal troubles. Disturbances in the sexual function are common in tabes; sometimes there is at the onset satyriasis, usually as the disease advances, there is loss of sexual vigor, and finally impotence. In connection with this, I may mention to you an interesting case which I saw today: A gentleman from near Chatham, Ont., has gradually become impotent, and the question has been raised by an eminent American specialist whether the loss of sexual power was not an early tabetic symptom. The man is powerfully built, accustomed to out-door life, had syphilis about fourteen years ago, and has abused his sexual powers to excess. For three months he has been on a strict anti-syphilitic treatment without any benefit, and he is now practically impotent. The testicles are soft and flabby, and there is a large varicocele. There are none of the tabetic symptoms presented by the case we have just considered, though he does complain of dragging pains at times in the legs. In rare instances, impotence is an early, perhaps initial symptom in tabes, but whether it is so or not, in this instance, time alone will tell. Dr. Bray, of Chatham, under whose care he is, will doubtless know in a few years. Possibly the varicocele may have something to do with his trouble.

You doubtless are aware that much discussion has taken place lately regarding the cause of tabes, and many facts have been brought forward by Fournier, Erb, Gowers, and others to show the close connection between it and syphilis. Statistics prove that considerably over fifty per cent. of all tabetics have had syphilis,[1] but whether this is simply a matter of association, or whether a definite causal relationship exists, is not yet clear. You should be especially careful in obtaining the history of a patient to ascertain if he has had syphilis, as the treatment may be thereby considerably influenced. There are some indeed who regard the occurrence of tabes as in itself a proof of the existence of syphilis, but this is an extreme view and not borne out by facts. In the case you have just seen we can obtain no positive evidence of infection; true, he has been *in the way of it*, having had gonorrhœa, and the death of three children, one with a general rash, is a suspicious circumstance, but he is an intelligent man, anxious to give all details and he seems quite certain that he never had a sore on his penis or any secondary manifestations. It is astonishing how reluctant some men are to acknowledge the pox. Even an intelligent physician will conceal the fact from his best friend and deceive him grossly, as in the following instance. A few years ago, after a medical dinner in London, the conversation turned on this very subject, tabes and syphilis, and one gentleman was very positive about the invariable association of the two. Our host stated that he had under observation a medical man, the subject of tabes, who offered a satisfactory refutation of this view as he had never had syphilis. I ascertained the name of the surgeon referred to, and to my surprise found that it was a man with whom I had been acquainted on the continent, and who at the time was under treatment for secondaries.

---

[1] In the Vienna Correspondence of *Canada Medical and Surgical Journal*, Dr. James Stewart states that Dr. Weiss found only ten syphilitics in one hundred cases of tabes.

Exposure and cold, especially with muscular fatigue, are believed to be potent influences in the etiology of tabes, and in this connection it is worthy of note that our patient has been much exposed to cold and wet when working at his trade as millwright, often up to his waist in ice-cold water.

From the fact that he has had lightning pains for over four years you may gather that even the initial stage may be very prolonged. Tabes is perhaps the most chronic of all nervous affections, and in individual cases it is impossible to predict what the course will be. This patient may not become *ataxic* for years; unfortunately for him, the optic atrophy will almost certainly be progressive and lead to total blindness. Occasionally the course of the disease is very rapid. I had arranged to show you another case to-day, a pronounced ataxic, with the characteristic gait, etc., but he sent word that he was too unwell to come. This man has had syphilis, has suffered from cerebral manifestations, and now for nearly two years has presented symptoms of tabes, the incoördination being now so great that he moves about with very great difficulty. When once established, the disease is, as a rule, hopelessly incurable; it is impossible to restore sclerotic nerve-tissue to the normal state. The most we can hope to do is to arrest the progress and alleviate some of the more distressing symptoms. Where there is a decidedly syphilitic history, as in the case I just referred to, a thorough course of mercury and iodide of potash should be tried. It has done him no good, but there are instances on record in which such a plan has been of material benefit. Of course, the remedies in vogue in the treatment of the disease are legion. At present great confidence is placed in nitrate of silver, in quarter of a grain doses three times a day, continued for months, intermitting every fifth week to prevent deposition of the salt and staining of the skin. It seems to relieve the pains, and in some cases the incoördination has disappeared during its employment. We shall put this patient on a prolonged course of the silver, and order galvanism to the spine. Rest is an important element in the treatment, but in many instances, as in this one, impossible to procure. When the electric pains are severe, friction (massage) is beneficial and in very bad spells, hypodermic injections of morphia.

I have no belief in the restitution by therapeutic means of a sclerotic tract in the spinal cord; as well might we hope for restitution of a group of sclerotic (cirrhotic) liver lobules. Curiously enough, even when decided amelioration does take place or a cure is apparently effected, the lesion in the posterior columns may remain unchanged. In one of the recent numbers of the *Archiv für Psych.*, Dr. Schultze reports a remarkable case which illustrates this. A patient of Dr. Erbs' was apparently cured, the ataxia and pains disappeared; absence of patellar reflex and slight vesical trouble alone remained. Twelve years after the appearance of the symptoms of ataxia, and eight after their disappearance, he died of poisoning. At the autopsy the posterior sclerosis was well marked in the lumbar section of the cord, and there was degeneration of the posterior root-zones in the dorsal and cervical regions.

The opinion is gaining ground that locomotor ataxia is not simply posterior spinal sclerosis, but a widespread affection of the sensory nerves; and taking this view the various peripheral nerve changes, the optic atrophy, which is so common, the occasional affection of the auditory, and the degeneration of the cutaneous nerves which has been described—all come in as part of the general affection.

ORIGINAL ARTICLES.

DEATH FOLLOWING THE EXTERNAL USE OF POWDERED BORACIC ACID.

Reported by L. D. Brose, M.D., Ph.D.,
PROFESSOR OF ANATOMY IN THE MEDICAL COLLEGE OF EVANSVILLE, IND.

A. B., American, æt. 31 years, admitted to City Hospital May 1st, for a large open sore on the outer surface of the right thigh. He stated that one year and a half ago he entered St. Mary's Hospital with an extensive cellulitis, involving the right leg and thigh, and that Dr. A. M. Owen had made an incision extending from just above the external malleolus to within a short distance of the great trochanter. The wound in the leg healed, but that in the thigh only partially closed, and finally he, of his own accord, left the house. He was next treated at the Poor Asylum, but left that institution before receiving any marked benefit.

After his admission to the City Hospital the hot iron was freely applied to the sore, followed by a poultice, and subsequently, for three days, a lotion of potassio-tartrate of iron. This was then discontinued, and replaced by the powdered boric acid, frequently dusted on, and renewed during the day. The next four days the wound improved rapidly, the granulations becoming healthy and very numerous. May 11th, just five days since the use of the acid, he complained to the resident, Dr. Hilsmeyer, of diarrhœa, when he administered pil. hydrarg., followed by an astringent. This seemed to check his bowels, and the potassio-tartrate of iron, which he had also been taking internally, was discontinued. The following day, the diarrhœa returning, he was given pulv. rhei, followed by tr. krameria. His mind at this time was clear, temperature normal, with slight frequency of pulse. This failed to check his diarrhœa, and the patient began to vomit his food. The granulations also assumed a sluggish appearance, and the boracic acid was discontinued for the iron lotion. The diarrhœa was finally controlled by an enema of tr. opii and argenti nitras, but only at the expense of increasing the vomiting, and large quantities of water and mucus were now ejected from the stomach whenever the patient made the slightest attempt to swallow either a solid or liquid. Carbolic acid, calomel gr. $\frac{1}{6}$, hydrocyanic acid, sodii bicarb., all in turn, failed to influence his stomach. May 15th, the following day after discontinuing the boric acid, the temperature in the mouth was 97.4°, pulse 105, intellect clear, and the patient complained only of great weakness. The eyes had a peculiar staring appearance, while the body was bathed in a cold, clammy perspiration. On being asked, he said that for several days past he had passed his water several times during the night, and this upon examination proved to be intensely acid, high colored, and without a trace of albumen.

Hypodermics of morphia and atropia were resorted to, which controlled an annoying hiccough and partially relieved the vomiting. May 16th, his temperature at 2 P.M. was 96° in the mouth, 98° in the rectum; tongue red, pointed, but moist; pulse 140, and almost suppression of the urine, which was drawn off by the catheter. A stimulating enema of whiskey and digitalis was given, after which the bowels, which had remained confined for several days, moved once. During the night of the 16th he vomited blood repeatedly, the pulse became very rapid and feeble, notwithstanding repeated subcutaneous injections of morphia and atropia, and death occurred on the morning of the 17th, at six o'clock, just three days since the last application of the boracic acid. At the autopsy, which was commenced by myself but completed by Dr. R. M. P. Ames, of the U. S. Marine-Hospital Service, the following notes were made: Lungs normal. Heart normal in appearance. The right ventricle contained a large clot, portions of which were ante-mortem in character. No valvular lesions. Stomach presented evidence of congestion, and the mucous membrane several spots of erosion. Intestines deeply congested and inflamed. Liver enlarged, especially the right lobe, which was much congested and softened. No reaction to tr. iodine. Gall-bladder greatly distended with bile. Spleen enlarged, and the pulp highly inflamed. Kidneys normal in size, and the capsule readily stripped off. Cortex on section of a yellowish hue.

Microscopical examination of liver and kidney: The former presented great swelling of the liver cells, which had lost their polygonal character, become very granular, and contained an increased number of nuclei. The interstitial tissue in the region of the hepatic artery and portal vein had undergone proliferation, and this, along with the wandered-in leucocytes, had in one instance progressed almost to abscess formation. Kidneys: cells highly granular and swollen. In many of the tubules a granular exudation is observed, evidently derived from the cells, and not due to their breaking down, as the cells themselves are seen occupying their normal relation to the basement membrane. Tube-casts are observed in some of the tubes that have been cut transversely. There is no appreciable interstitial involvement. In both the liver and kidney sections much bile pigment is abundantly scattered throughout the tissues.

As a summary, the prominent symptoms may be mentioned: Great gastro-intestinal inflammation, giving rise to obstinate vomiting and purging; a clear intellect up to the last, along with staring eyes, a very rapid and feeble pulse, low temperature, and intense acidity of the urine. Unfortunately the reaction of the blood, saliva, and bile was not taken.

A CONTRIBUTION TO THE PATHOLOGY OF CHOREA.

CHOREA OF SEVEN YEARS' DURATION; AUTOPSY; LESIONS OF BRAIN, CORD, AND HEART; MICROSCOPIC INVESTIGATION.

BY HENRY J. BERKLEY, M.D.,
OF BALTIMORE, MD.

THOUGH chorea has been classed by the latest writers as a functional trouble, observations have been recorded in which there were palpable lesions of brain and cord, not unlike the present one; and now that Charcot and others have discovered well-marked organic disease in long-standing cases of hysteria, would it be unreasonable to expect to meet it in chorea St. Viti, a state most evidently due to some irritation of the nervous centres. The present example, deficient as it is in several points of the necropsy, may help somewhat to lighten the obscurity.

Alice Bradford, æt. 41, married, and mother of six children, received a severe fright seven years ago on witnessing the committal of a murder. Within a few hours afterward choreic movements began, which soon became very severe, and continued so till the end of her life. No previous history beyond what has already been given could be obtained.

Present state, October 1, 1881: The mental condition has been for a long time previous, and is now one of general weakness. She is exceedingly stupid, irritable, and at times will not answer any question addressed to her. The body is well nourished, food being taken with avidity: its deglutition is accompanied by a peculiar jerking movement of the pharyngeal muscles. Thirst is intense, the quantity of liquid daily drank amounts to several quarts. The skin is frequently covered by an abundant sweat. All the voluntary muscles participate in the spasms, which are very severe, but not more intense on one side than the other. A cup of water placed in the sufferer's hand and directed to be drank exhibits all the bizarre incoördinated movements in perfection, before arriving half-spilt at the mouth. Slight muscular twitchings persist during sleep. Owing to the extreme stupidity of the woman tests of sensation could not be made with any satisfaction, but it is reasonable to suppose that analgesia was probably present, since the severe bruises produced by striking the arms and legs against the bedside during the choreic spasms were never complained of. The voice is almost inarticulate, jerky, and often interrupted by spasms of the laryngeal muscles. The pupils are normal or very slightly contracted, and do not readily respond to light. The heart participates in the muscular unrest, but there are no valvular murmurs. The pulse is irregular and rapid.

About the middle of October she was noticed to be becoming more stupid than usual, and also to manifest less desire for food; this dulness gradually increased till coma became well developed. The respiration, from being normal or slightly accelerated, grew stertorous, and the heart's action became more feeble. Nevertheless, at times the choreic access continued with unabated violence; the patient in the severity of the exacerbation would strike the arms and legs so violently against the bedside as to bring the blood.

A week before death the stertor grew still more intense, and the heart's action more feeble; the sufferer remaining comatose the entire time, so that it was with the greatest difficulty that she could be aroused sufficiently to be given nourishment. The coma continued without break till death, which happened on the second of November. It was marvellous to witness how the muscular unrest continued in the nearly unconscious condition in which she lay for the week preceding dissolution. No delirium was ever manifest during the entire time she was under my charge. No emaciation was ever visible, and the only surface lesions were a large eschar over the lumbar region produced by the constant friction to which the parts were exposed, and a few bruises on the elbows and legs. I should note that the injuries received healed readily when preserved from further irritation.

The nurse tells me that one night, about six weeks before death, during a violent exacerbation of spasm, she forcibly struck the back of her head and neck against the low iron bedstead upon which she was lying.

Post-mortem (*eighteen hours after death*).—Weather cold, rigor mortis well developed, measurements of the limbs showed no difference between them. The cranium was first examined. The skull was symmetrical, of ordinary thickness, with the diploë well marked. The dura-mater was normal, no congestion was visible in it, nor were the sinuses filled with blood. No adhesions were present between it and the pia-mater. The latter membrane was thin, transparent, easily detached from the convolutions, natural everywhere, except between the hemispheres, where there had been old inflammation, the outer two surfaces being adherent for one and a half centimetres above the corpus callosum. Several ounces of serum tinged with blood were found in the arachnoid spaces, mostly collected at the base of the brain. No embolisms or other lesion of the arteries could be discovered.

The brain was considerably atrophied, and did not fully occupy the cranial cavity. The cerebral substance was of a softer consistency than is usually found in so fresh a cadaver. Transverse sections were made vertically from before backward. The puncta vasculosa were slightly dilated, and the gray substance also seemed unnaturally vascular. The white matter, further than its vascularity, was normal, as were likewise the caudate and lenticular nuclei and claustrum. The thalami optici were discolored, of a reddish-brown hue, the right ganglion being much more vividly so than the left. This discoloration (in the vertical sections) was circumscribed over about one-half of the centre of these ganglia, the peripheral portions being intact. The vessels of the thalami were abnormally large and empty of blood. Several drachms of serum escaped when the lateral ventricles were opened.

The cerebellum was normal; the bulb was very small, though its contour was as usual.

Spinal Cord.—The laminæ were cut and the membranes exposed. To the eye, the dura-mater offered no anomaly till the arch of the fifth cervical vertebra was reached; here a subperiosteal abscess had formed (most probably a sequel to the severe blow received by the neck some weeks previously) on the right lamina of the arch, which had opened internally, its contents spreading over the surface of the dura. The pus extended from the diseased vertebra to the base of the skull, the quantity being about half an ounce; none had passed below the fifth cervical vertebra, and none into the cranial cavity. The pia-mater was transparent and normal.

The medulla spinalis was very hard, so much so, as to give a clean transverse section with a dull scalpel, did not project beyond the membranes, was atrophied in its entire length, though particularly so in the mid-dorsal region, where measurements gave transversely seven millimetres, and antero-posteriorly six millimetres. The cervical region in the vicinity of the abscess was slightly flattened from before backwards, though the compression had not been sufficient to produce a trace of softening. The anterior median fissure, especially in the greatly wasted parts, presented a wide V-shaped fissure with its apex upon the white commissural fibres. The cord showed no other macroscopic lesions. The spinal nerve-roots presented no aspect of degeneration.

Thoracic Viscera.—In the larger bronchi appeared evidences of chronic bronchitis; otherwise the lungs were normal. The heart was enlarged, without external deposits of adipose tissue. The muscular walls of both right and left sides were thin, and when taken between the thumb and forefinger crumbled like spleen or liver substance. The valves were perfect in their coaptation, and exhibited absolutely no signs of preëxistent inflammation, having neither lymph nor granulations upon their margins, nor lymph patches on the substance of the valves themselves, nor did they present the slightest trace of thickening. The pericardium and endocardium were sound.

Abdominal Viscera.—All but the kidneys were natural, they presenting a deeply congested appearance.

Portions of the cortex from the ascending parietal, second frontal, and an occipital convolution, white matter, ganglia, cerebellum, pons, heart, and entire spinal cord were preserved for histological investigation. They were carefully hardened in a two per cent. solution of bichromate of potassium, frequently changed, and afterwards in alcohol. The majority of the sections made were stained in ammonia carmine; occasionally osmic acid was used to note if any variations could be detected in preparations by different reagents. The specimens were all compared with normal ones, to prevent mistakes.

Microscopic Examination — the Brain: Cortex and White Matter.—The first striking abnormality that presented was a marked dilatation and thickening of the middle-sized and smaller arterioles of both white and gray matter. In this thickening, intima and adventitia were equally involved. Around many of the vessels, the perivascular spaces were large, occasionally containing amyloid corpuscles. The capillaries were distended with red blood-cells, and here and there around a large number of them, particularly those of the cortex, were minute, almost circular spots, which colored dark brown with osmic acid, and were almost untinged by carmine, evidently minute depots of softening resulting from impaired circulation, containing a few leucocytes, with the cerebral tissues totally broken down, the cortical cells in the ulterior stages of pigmentary degeneration, the nerve-fibres disintegrated. The extent of these necrobioses was very limited, the largest scarcely extending one-thirtieth to one-twenty-fifth cm. beyond the perivascular space. Upon the walls and in the outer sheaths of some of the arterioles, numbers of white blood and granular corpuscles were found.

The cortical cells frequently show a considerable degree of granular alteration, best marked in the smaller multipolar cells, though not confined to them, for a considerable proportion of the large pyramidal cells had totally deteriorated, leaving only a small mass of granular matter; but in others scarcely any variation from the normal could be seen. The processes of the cortical cells that remained sound were well developed, and their nuclei were easily discerned, while, on the other hand, the arms of the altered cells were very fine, or had disappeared entirely, as had likewise many of their nuclei. No difference existed in the cell-state between the motor and sensory portions of the brain; hence no mention is made of special convolutions. There was no appreciable increase of the neuroglia.

A vast majority, though not all, of the nerve-fibres of the brain, both in the motor and sensory regions, exhibited great varicosity, the dilatation in spindle and barrel-form predominating, the knotty swellings being far more frequent than is found in a healthy brain. Frequently through the varicosities the cylinder-axis could be distinctly seen, itself not enlarged, following a wavy course, most frequently towards the side of the swollen medullary sheath, while in other fibres it was very indistinct or visually absent.

Through cortex, white matter, ganglia, and cord, small, reticular, honey-comb spaces, some larger, some smaller, but none of any great size, were met with, crossed at irregular intervals by bands of the tissues proper to whatever region the section under the field of the microscope happened to be from. These vacuolar spots formed irregular lines, sometimes running quite a distance, crossed at intervals by the tissues, at others short, all empty of any discernible substance.

The Ganglia.—The optic thalami claimed the chief attention. The general vascular dilatation and thickening were here very well seen, and in the outer coats of many of the arterioles a considerable nuclear proliferation was observable. Rather frequent minute necrobioses marked the only change in the parts surrounding the vessels, except that in a few lymph-sheaths there were amyloid corpuscles.

The entirely degenerated cells were less numerous than in the cortex; in the majority, the granular matter was confined to a single large lump in one angle, with a few scattered granules through the remainder of the cell, the nucleus clear and distinct, while in the totally deteriorated ones, cell, nucleus, and prolongations had disappeared, leaving only a small mass of pigmented matter. The axes-cylinders of the fibres traversing these bodies were considerably swollen, though the myeline itself presented no unusual variation. No hyperplasia of the neuroglia has yet been noticed. The cerebellum was free from all lesion, except a few vacuoles.

The Bulb: Region of the Pons Varolii.—The intricate labyrinth of nerve-fibres throughout this region seemed to be normal in all respects; the pyramidal and other well-marked fasciæ showed no degenerative change; among the myriad cells in the formatio-reticularis, hardly an altered one could be found; there was no increase of neuroglia; even the bloodvessels did not show nearly so great thickening as in other localities. The appearance was greatly different in the neighborhood of the floor of the fourth ventricle. Irregularly scattered through the majority of the nuclei of origin were numerous cells filled with granular matter, and atrophied greatly; in a number, all vestige of nucleus and nucleolus had vanished; of others, all that remained was a small mass of granular matter, showing where the cell had been.

All the nuclei of the trigemini were apparently sound, while the nuclei proper of the facialis, and that common to it and to the abducens, contained a number of granular atrophied cells among the normal ones.

Superior and Middle Olivary Regions.—The scattered cells of the median portion of the medulla and the nuclei along the median raphė had suffered somewhat more from the disease than those immediately adjacent to the floor of the ventricle, they showing a well-marked alteration in nearly all of their cells, whilst in the superior portions of the hypoglossal and glosso-pharyngeal nuclei a considerable proportion of the cellular elements remained normal. However, in the posterior median nuclei of the acustici, the majority of the cells had degenerated. The nuclei of the vagi, too, showed a large number of altered cells. It is noteworthy that, as the section advanced towards the lower portions of the vagi and hypoglossal nuclei, the cellular change became less and less, disappearing almost in the inferior cells of the accessorius. The olivary bodies, as far as fibres and cellular elements went, were perfectly healthy; their cells were distinct, with nucleus and nucleolus well developed. The nerve-fibres passing to these bodies were also intact.

Inferior Olivary Region.—On each side of the posterior fissure the nuclei of the hypoglossi were clearly depicted, containing not many degenerated cells, while the inferior facial nuclei of L. Clarke, immediately to the outside of the preceding, were much more diseased than any of the other nuclei of origin, all their cells being highly granular and atrophied. Upon the right side the change was greater than on the left, a considerable number of the cells having completely disappeared, judging from the opposite side and from normal preparations. Indeed, throughout the right half of the bulb, the diseased state was somewhat more intense than on the left. The superior portion of the nuclei of the accessorii contained a good many highly altered cells, which progressively decreased in their lower portions. The gelatinous substance and descending roots of the fifth showed no trace of degeneration.

The vessels of the medulla were all dilated, and filled with blood, though without much thickening of their walls. The extreme external part of the olives, but within the cell-layer, is occupied by a large irregular space, partly filled by an arteriole and vein. Around a number of the vessels of the pons and medulla were collections of amyloid corpuscles with an occasional minute area of dead tissues. There was a noticeable proliferation of the neuroglia in the lower tracts of the medulla.

Spinal Cord.—Immediately after the passage of the medulla spinalis through the foramen magnum, the hyperplasia of the connective tissue became exceedingly well marked in the antero-lateral columns, so much so as to give those portions of the cord a decidedly sclerotic appearance, with here and there an occasional patch of true sclerosis, in which the nerve-tubes were reduced to an exceedingly small number, with the axis-cylinders much hypertrophied, and with very narrow circles of myeline around them.

The vessels of this region were much more thickened and less dilated than in the hemispheres or bulb, while many of them were surrounded by amyloid bodies, and some with areas of necrotic tissue around them. The vessels of the gray matter seemed not so greatly involved, though in a single section a large vein crossed transversely the anterior cornu, surrounded by amyloid bodies and a trace of softened substance.

The cells in all the different tracts of the horns looked to be nearly normal. The central canal was entirly obliterated by an abundant proliferation of its epithelium.

Cervical Enlargement.—The cell lesions were better marked here than in the higher sections of the cord; a few here and there had entirely degenerated, without nuclei or protoplasmic processes, with their bodies reduced to a small mass of granular matter. A small number of the cells presented a nodular aspect, their prolongations ending close to the body, their nuclei present, though seen very indistinctly. The greater portion of the cells of the horn contained some granular matter, and showed an unusual yellowish tinge. In one gray column I counted twelve very granular and nodular cells amongst a total of seventy-three contained in the horn.

The hyperplasia of connective tissue and Dieter's cells is here considerably less than in the higher tracts, but there is still an abundance of it. The change in the vessels seems to be much in proportion to the amount of neuroglia. The central canal continues the same—that is, occluded.

Dorsal Cord.—The increase of connective tissue and Dieter's cells again became much more noticeable, heavy trabeculæ extending from periphery to centre, densest in the anterior and lateral columns. The nerve-tubes were much scarcer than is usual, compared with normal preparations, their places being filled with neuroglia cells and trabeculæ, the tubes themselves showing some evidences of sclerosis in an occasional swelling and irregularity of the cylinder-axes, and a varicose or diminished state of the myeline. Longitudinal sections showed the absence of the axis-cylinder from its sheaths in a small proportion of the fibres. The spindle swellings were much more infrequent than in the brain.

The thickened vessels still continue, and are even more numerous than in the other regions previously examined. The centre of the gray cornu on one side is occupied by an arteriole having a lumen only one-third the transverse diameter of the vessel. Amyloid bodies are still found.

The cell degeneration in the dorsal cord is confined to an occasional one in each section, principally in the median and postero-lateral groups. The central canal was entirely closed in all preparations of the dorsal cord. Throughout the entire gray columns, the nerve-fibres running longitudinally in them had to a large extent vanished.

Lumbar Region.—The augmentation of the neuroglia has now comparatively subsided, being only thinly scattered over the lateral and anterior tracts. The fasciculus of Türck on the right side showed the sclerotic condition more than on the left. The vessels are not so highly thickened as in the superior portions of the cord; the artery in the centre of the gray horn still continues, and holds the same course as in the dorsal tract. The spots of softening around the vessels, which had become more and more scarce as we descended the cord, now entirely disappeared, as also did the vacuolæ.

The motor cells of the anterior horns, on the contrary, revealed the degenerative process more plainly than in any other region. Frequently whole groups of cells appeared diseased, and it was infrequent to meet with an approximately normal one, an event not before met with in any portion of the cord. The central canal is still occluded. Through the entirety of the medulla spinalis the fasciæ of Goll and Burdach were much less involved by the increase of neuroglia, and, indeed, in many places had been completely spared. The posterior horns also were normal throughout the cord.

Nerve-roots.—The root-fibres of the trigeminus were perfectly free from any abnormal condition. The roots of the spinal nerves showed a partial granulo-fatty degeneration of the sheath of Schwann, though the axes-cylinders were normal in all respects. Very few of the nerve-tubes had escaped the alteration entirely.

The Heart.—Isolated fibrillæ of this organ revealed slight fatty degeneration of the primary muscular fasciculi. The transverse striation was also indistinct. Teasing was performed with great difficulty, the muscle breaking down into irregular masses under the slightest pressure of the needles.

Résumé.—In the brain, general dilatation and thickening of the arterioles; small gangrenous spots around many vessels; amyloid corpuscles in the lymph-sheaths; vacuoles in white and gray matter; varicosities of the sheath of Schwann, and absence of axis-cylinders in the nerve-fibres; and complete pigmentary degeneration of a large number of the cortical and ganglionic cells, with loss of the prolongations.

In the bulb, the vascular lesions are much diminished; necrobioses rare; amyloid bodies in some lymph-sheaths; alteration of the nuclei of the facial, abducens, hypoglossal, glosso-pharyngeal, acusticus, vagus, accessorius, and inferior facial of L. Clarke, and other groups and scattered cells centrally situated along the median raphé.

In the superior cervical cord, increase of vascular changes; necrobioses frequent; partial sclerosis of antero-lateral columns; ganglionic cells comparatively healthy. In the cervical enlargement, increase of cellular change, with diminution of the connective tissue one.

In the dorsal cord, immense augmentation of the diffused sclerotic state in the anterior and lateral columns; vessel-walls much hypertrophied; little change in the ganglionic elements; varicosities of the medullary sheaths, with an occasional swelling of the axis-cylinder, and its complete absence from the fibre in others. In the lumbar cord, degeneration of the majority of the motor cells; increase of neuroglia less marked. Occlusion of the entire central canal; posterior horns sound throughout the cord; no embolisms in any of the vessels; granulo-fatty changes in the sheath of Schwann in the spinal nerve-roots: fatty degeneration of the muscular fibrillæ of the heart.

Commentary.—The histological results of the present observation do not differ widely from ones that have been previously made in chorea. The cell degeneration, thickening of the adventitia and intima, or dilatations of the vessels, increase of the neuroglia, etc., have all been seen by other observers, notably Rokitansky, Steiner, Dickinson, Elischer, and Golgi; but what has not been previously mentioned so far as I am able to discover, is the inflammatory state of the nerve-tubes of the brain and cord, the vacuolæ, the degeneration of the nuclei of origin in the bulb, the fatty state of the heart. Nor has the same state of the spinal root-fibres been noticed, except in the case of Elischer,[1] who found increase of the neurilemma, and the nerve-fibres covered as with hoar frost and glassy; a condition which, though not analogous, is yet sufficiently so to show that there is an alteration in the peripheral nerves. Contrary, too, to the reports of Elischer[2] and Golgi,[3] the posterior white columns were, to a great extent, saved from the general diseased condition of the cord.

In the pigmentary alteration of the nuclei of the vagi, can we not see an explanation of the common implications of the heart in the choreic movements, with or without valvular trouble; *the disease causing loss of the inhibitory power of the pneumogastric nerve, hence the irregular action of the heart muscle?*

Again, the cell degeneration and vacuolous state (showing atrophy of the cerebral matter) of different portions of the encephalon, particularly the cortex, may readily account for the mental alienation almost universally seen in St. Vitus' dance when of any duration, and for the fact that mania and paralytic dementia sometimes follow it.

In concluding, I sincerely thank Dr. I. Bermann for his kind assistance in corroborating and confirming my results of the examination of the cerebrospinal axis.

---

A CASE OF HEPATIC ABSCESS DISCHARGING THROUGH THE BRONCHIAL TUBES; RECOVERY.

By JAMES ORR, M.D.,
OF TERRELL, TEXAS.

A. D., aged 36, stout and healthy, after several days' illness, sent for me March 8, 1882. I found him restless and anxious; skin hot and dry; temperature 103°, pulse 90, respiration 22; intolerance of light and noise; nausea without vomiting; urine scanty and high colored; tongue dry and red; conjunctiva slightly yellow; intense pain over stomach and right hypogastric region; bowels constipated.

The case was treated as one of gastro-duodenitis; ordered pills of morphia one-sixth of a grain, conium ext. one-half grain, and ext. hyoscyamus two grains, every four hours; also ten grains of acetate of potassium in two drachms of liq. ammon. acetatis every four hours. Diet light, and bowels to be moved every alternate day by enema.

Under this treatment, he improved rapidly. all his bad symptoms subsiding so much that he sat up on the twelfth for an hour or more. The next day, however, his fever returned, and grave symptoms manifested themselves at once, his temperature running up to 104°; pulse 120, respiration 28; intense nausea, with vomiting and diarrhœa; increased pain and tenderness over region of stomach and liver, the latter being swollen to nearly double its usual size, and very tender on pressure. Ordered morphia, grain one-sixth, and oxalate of cerium, grains five, for relief of pain and nausea, as occasion required; added full doses of tinct. digitalis to the mixture of acetate of potassium and spiritus Mindereris, previously given; also pills composed of ext. nux. vomica one-eighth of a grain, ext. conii. one-half grain, and ext. hyoscyami two grains every four hours. Blister three by four over liver.

March 15.—Nausea and vomiting have ceased; nervous symptoms less troublesome; pain under control; other symptoms unchanged, except the patient is completely discolored by jaundice, his entire body being as yellow as an orange. Continued treatment as above, substituting aconite for digitalis in the febrifuge, and increasing the area of blister over liver.

18th.—All symptoms improved, only the liver does not decrease in size. Ordered iodide of potassium in calisaya as tonic and alterative, with careful attention to diet and regimen. The skin and kidneys were kept rather active in their work of elimination, in which they were eminently successful, all the discoloration having disappeared in ten days, but in the matter of reducing the size of the liver, I was not only doomed to disappointment, but soon learned that I had an abscess to deal with. The acute symptoms having subsided, tonic treatment was now resorted to, a succession of blisters applied over the diseased organ, and the morphia with oxalate of cerium continued for relief of the pain and nausea, which were constantly recurring. Under this treatment, the general condition improved, but no sign of adhesion could be detected, nor could any fluctuation be felt.

April 9.—Discovered acute circumscribed pneumonia in the lower lobe of right lung, which, however, gave but little trouble and soon yielded to treatment. On the 17th I was called away and did not return till the 22d, when I found my patient very much worse, great prostration having set in, while his countenance wore a livid and anxious aspect; temperature 100°, pulse 140, respiration 30; complained of great pain in the lower part of right lung. Has a constant distressing cough with expectoration of tough glairy mucus in small quantities. While examining him he coughed up about a teaspoonful of what appeared to be almost pure bile, which led me to the conclusion that the abscess was going to discharge through the bronchial tubes. From this time the cough became constant and harassing, the expectoration rapidly increasing; in twelve hours it amounted to a pint of what seemed to be an admixture of bile and pus with a few shreds of broken-down tissue.

24th.—Total amount of expectoration up to this time is two quarts, the character of which has not changed; his constant effort to expel the pus from his bronchial tubes has greatly reduced his strength despite the large quantity of brandy and ammonia given. Temperature 98°, pulse 140, respiration 46; tongue yellow from expectoration, skin cool and moist, urine scanty and high-colored, bowels constipated, considerable thirst and anorexia. The liver, which has all along been swollen and hard, has greatly diminished in size with a distinct depression several inches in diameter, having well-defined margins, indicating where the abscess existed. During the day another pint of matter was expectorated, making five pints in all up to this time. The cough and expectoration now began to subside rapidly, and by May 8th had ceased altogether, the patient having greatly improved under the judicious use of wine of pyrophosphate of iron, Huxham's tincture, and dilute phosphoric acid. At this time, March 1, 1883, he enjoys better health than ever before, presenting no trace of his former disease, except a slight depression over the margin of the liver, and somewhat prolonged respiratory murmur in right lung.

The rapidity with which this very large abscess emptied itself leaves no doubt that a bronchial tube of considerable magnitude was perforated, to reach which the pus was forced to travel some distance in a direction contrary to gravitation, which taken in connection with the rapid and complete recovery of the patient, marks it as a case of no little interest to the practitioner and illustrates the wonderful curative powers of nature when given a fair chance.

MEDICAL PROGRESS.

Splenectomy.—Rather more than a year ago Mr. Herbert Collier published a table of twenty-nine cases of removal of the spleen, showing eight recoveries, but an invariably fatal result when the splenic disease was associated with leucocythæmia. From this fact, Mr. Collier drew the inference that the operation was not justifiable in cases of leucocythæmia. In some quarters exception was taken to this view, and it was pointed out that the operation had been employed when the disease was too far in advance, and that it was wrong to infer that the same mortality would attend it if performed at a quite early period and before the general blood changes were far advanced. A case has occurred in the practice of Franzolini, of Turin, which appears to support this view. His patient was a young woman, twenty-two years of age, whose illness commenced with pain and distress in the left side of the abdomen two years before she came under his care; after eighteen months a large splenic tumor was noted; and some months later an increase of leucocytes in the blood, which at the time of the operation were five times in excess of the normal. The spleen was removed through an incision in the linea alba, its artery and vein were ligatured separately; it weighed after removal and when emptied of blood fifty-two ounces. The leucocythæmia gradually subsided, and had disappeared altogether in four months. This case is certainly encouraging. Dr. A. Blum has recently written an article upon the whole subject of excision of the spleen in the *Archives Générales de Médecine.* His conclusions, based upon a study of the recorded cases, are that while the operation of splenectomy is practicable and is compatible with complete recovery, it is so often fatal from hemorrhage or shock that it is but rarely indicated. He considers that it is not justifiable in cases of splenic cysts, because they can be cured by other and milder measures; or in cases of hypertrophy, whatever its cause; or in cancer of the organ, on account of the very high mortality. But he points out that in cases of movable spleen with marked and severe symptoms, the operation is comparatively easy and successful; while in cases of hernia of the spleen following an injury, the removal of the herniated portion is so successful that the surgeon is fully warranted in undertaking it.—*The Lancet*, July 28, 1883.

Jamaica Dogwood.—Prof. Ott, after a number of experiments with this agent, concludes that the sleep produced by it has the same characteristics as that produced by bromide of potassium. He has experimented on himself with it, and found that after taking a spoonful of the fluid extract of the bark, sleep came on quickly, and lasted for three hours. On awakening, there were no disagreeable sensations, such as are felt after taking opiates. Its active principle produces mydriasis, not in the same manner as atropine, but by an energetic action on the vaso-motor nerves. The fluid extract may be given in doses of about fʒss. It may be combined with double its amount of syrup of bitter orange-peel, or with double its amount each of distilled water and syrup.—*Therapeutic Gaz.*

Prophylaxis of Puerperal Fever.—The paper by Swiecicki, in *Centralbl. f. Gynäk.*, as to the time during which a physician should abstain from obstetrical practice after having made an autopsy, or after attending a case of puerperal fever, has brought out a communication from Hermann Löhlein to the Gesellschaft für Geburtshulfe und Gynäkologie zu Berlin, in which he replies to Swiecicki. It will be remembered that Swiecicki concluded that the proper time for this self-quarantine was eight days. It is clear, says Löhlein, that if this rule be rigidly carried out, grave consequences and great inconveniences will result. Hospital physicians would be unable in many cases to perform their duties, and medical students who are dissecting would be excluded from hospitals; for if the performance of an autopsy is a sufficient reason for quarantining a physician, the opening of an abscess, or examining a case of cancer of the os, is also sufficient, and endless inconveniences would result from this practice. He believes that strict cleanliness and proper antiseptic precautions are all that are necessary.—*Centralbl. für Gynäk.*, No. 23, 1883.

FRITSCH, in commenting upon Löhlein's paper, upholds him. He has followed these methods for ten years, and has had no serious cases. In 1873 he attended his brother for five months, who had coxitis and profuse attendant suppuration. After each dressing, he thoroughly disinfected himself with a six per cent. solution of carbolic acid, and though during this time he attended two hundred and forty obstetrical cases, there was not a single death, and no case of severe illness.—*Idem.*

THE TUBERCLE-BACILLUS IN THE AIR.—DR. C. THEODORE WILLIAMS recently selected one of the ventilation shafts at the Brompton Hospital for Consumption in which the flues of several wards converge, and in which extraction takes place at the rate of 300 to 400 feet a minute. In this current he suspended glass plates smeared with glycerine for a period of five days. The plates were then washed with distilled water, the fluid mixed with a little mucilage and evaporated down to half, and the residue tested for bacilli, which were found in fair abundance.—*The Lancet*, July 28, 1883.

STATE OF THE GUMS IN PREGNANCY.—M. DELESTRE has observed that not only in pregnancy, but during the menstrual periods, the gums in the female are congested, swollen, and softened. The gingival troubles commence about the second month of pregnancy. Didsbury describes three degrees of gingivitis of pregnancy. In the third, the gums are so inflamed that they have a reddish-violet color, are swollen, and the interdental portions are clearly shown. The tartar and epithelial *débris* accumulate around the teeth. This inflammation may extend to the alveolo-dental periosteum, for the teeth seemed to lose their lime, become elevated, and may fall out. This gingivitis is situated particularly in the anterior portion of the jaws; it rarely goes back of the canine teeth. Only the convex surface of the jaws is attacked. The treatment should be energetic; the tartar should be removed and the inflammation treated by astringent preparations, chlorate of potash, etc., and in grave cases with tincture of iodine, chromic acid, and hydrate of chloral mixed with some astringent tincture.—*Journal de Méd. de Paris*, June 23, 1883.

FEEDING IN CHOLERA.—DR. B. WARD RICHARDSON, in a recent communication to the *Medical Times and Gazette*, Aug. 4, 1883, says that he has been led to the conclusion that every fatal sign and every danger in cholera is due to the one simple act of the removal of water from the tissues, and especially from the nervous structures; to disturbance of nervous action by that removal; and to excessive reduction of heat, sensible and latent, from the body.

The treatment suggested during collapse, and based on these views, introduced the consideration of the plan of feeding by the veins, and of intra-peritoneal injection.

The lines of treatment, as they appeared and, with some additions, appear to him, were much the same as should be pursued in cases of exposure to extreme cold, where the body has been brought to several degrees below the natural standard of heat, and where, owing to the cold, the surface of the body is blue, the blood all but stagnant, and the consciousness reduced or lost. In such a case it would be folly to charge the affected person with cold, iced drinks, for by such means the temperature of the body would possibly be further reduced. In such a case it would be folly to plunge the person into a hot bath, for although there might, thereupon, be a sudden reaction, there would be no source of supply of heat, but merely a heat shock or stroke, under which the remaining vital powers would be called into sudden activity, to cease directly in death—the glacial form of inaction and rigidity, which is not of necessity fatal, being transformed into the pectous change, or true rigor mortis of the nervous, vascular, and muscular fluids, from which there is no known mode of resolution. In such a case it would, it seemed to him, be also useless to place the affected person in the hot-air bath, because exposure to heated air, under conditions in which the capacity of the blood to circulate freely is lost, would only tend to increase the danger of coagulation of the blood in the body, and, by quickening evaporation of water from the respiratory surfaces, to intensify the exhaust of water from the body.

The first point of practice in the collapse was, then, he thought, to place the sufferer in a medium temperature, not below 50° and not above 60° Fahr., so that neither the chilling action of cold nor the exhausting action of heat should exert a destructive influence; though heat, he thinks, is really the more dangerous of the two—a suspicion which the experience of cholera in tropical temperatures too fully confirms.

The next point of practice in the stage of collapse, which was suggested as the most rational, was that of feeding. He himself has succeeded in administering a quart of fluid per hour to the person stricken with cholera; and as the complaint of thirst is a common complaint there is never much difficulty in the persuasion.

The fluid to be supplied should, he holds, on all rational grounds, be one that shall fulfil two purposes. It should not make the body cooler by extracting heat, it should not produce local reaction by instant excess of heat; but it should be supplied after it has been raised from fifteen to twenty degrees above the animal temperature. I had often seen vomiting re-excited after that symptom had considerably decreased from the simple process of administering a drink too heated or too stimulating.

Taking advantage of the fact that crystallizable fat when mixed with albumen can be dissolved by the heat of water, which heat it fixes in becoming soluble, and gives up again on solidifying, he set to work to produce a food having the properties named. After numerous attempts the following proved most successful:

Take of pure stearine two ounces by weight; of best fresh butter, two ounces; of whites and yolks of eggs, well beaten up, eight ounces; of carbonate of soda, twenty grains; of common salt, eighty grains; of distilled water, two ounces.

In preparing the food, first dissolve with heat the stearine and the butter until they are both melted, then add the carbonate of soda and common salt to the eggs, and when these salts are dissolved in the egg-fluid, mix it with the oily fluid, taking care that the latter is not of a temperature above 140° Fahr. Let the whole cool to a soft consistence, and finally on a slab or a board, rub in the water with a broad spatula. The compound may now be placed in a wide-mouthed jar; in a little time it settles into a moderately hard mass, and is ready for use.

In administering this compound, take one ounce, place it in a large breakfast cup, and rub it up equally with a teaspoonful of glycerine or a teaspoonful of honey. Next pour upon the mass three ounces of distilled water, *actually boiling*, and incorporate well. The solid substance will now quickly and evenly dissolve, and will be at once so cool that it can be taken as a pleasant drink, like a broth in flavor.

Feeding by the Veins.—When feeding by the mouth is impossible, the next indication in the stage of collapse is to feed by the veins. In using this term he wishes to make a difference between mere injection of the veins with watery fluid and feeding by the veins. His proposition was, and is, *to feed*—to feed in the same way, as nearly as can be imitated, as the venous system is fed in health from the alimentary canal through the thoracic duct—slowly and steadily, so as to supply food as well as water.

Up to this time we have been content to inject warm saline solutions into the veins. The results have been often astounding, almost always delusive. In some instances it has seemed as if the injection has restored the dead to life, but the collapse has only too surely recurred.

The reason why certain immediate but not lasting benefits have followed these injections is, that they have been injected after the fluids used have been heated up to, or above, bloodheat; the heat thus supplied has been the underlying basis of the transient success.

ACTION OF MORPHINE ON THE INTESTINE.—L. M. PETRONE, in the course of some experiments on the action of sodium, potassium, and ammonium on the muscular fibres of the intestine, has indirectly demonstrated that morphine does not act on the terminal filaments of the splanchnic nerve, or upon the nerve trunks, but upon their central origins. The question may then be asked, Is the action of morphine on the intestine similar to that of digitalis on the heart? Nothnagel has answered this affirmatively; he has demonstrated experimentally that morphine, like digitalis, moderates, checks, or suspends nerve action in small doses, and in large doses paralyzes it. Nothnagel's experiments were repeated by Petrone, who concludes that small doses of morphine stimulate the terminal filaments of the splanchnic, whilst large doses paralyze them.—*Annali Univ. di Med. e Chir.*, June, 1883.

FIBROMA OF THE VAGINA.—In the *Boston Medical and Surgical Journal* for August 16, 1883, DR. EDWARD T. CASWELL, of Providence, records the case of a young lady, who was soon to be married, and who had been aware of some obstruction in the vagina for about two years. Latterly the obstruction had seemed to increase. There had been no pain, and no disturbance of the menses. Some inconvenience was experienced in walking, and some in sitting. On examination he found a tumor in the middle line of the anterior wall, over the course of the urethra, as large as a pigeon's egg, its anterior extremity being about three-quarters of an inch back of the meatus. It was not sensitive to pressure, and had a slightly elastic feel. An operation was advised for many reasons, not the least of which was the relief from anxiety that it would afford the patient in view of her approaching marriage.

A single incision in the middle line enabled him to easily enucleate the tumor, which measured in its long diameter about one and a half inches, and about three-quarters of an inch in each of its other dimensions. Under the microscope it proved to be a fibroma. There was but little hemorrhage, and the wall of the urethra was uninjured. Two or three sutures of catgut, with a small piece of drainage-tube, some absorbent cotton, and a napkin, were all that was required in the way of dressing. Carbolized injections were freely used, and the catheter passed for three or four days. The tube was removed on the third day. The recovery was uninterrupted, save for a slight hemorrhage on the day after the operation, which was checked by an injection of hot water. The wound was entirely healed by the eighth day, and the patient dismissed on the tenth. Except for the slight discharge of the first few days the young lady was conscious of no departure from her usual condition of health.

RESECTION AND DISARTICULATION OF THE INFERIOR MAXILLA FOR CENTRAL SARCOMA; EXTIRPATION OF THE PAROTID AND SUBMAXILLARY GLANDS.—PROF. ANDREA CECCHERELLI reports the following interesting case occurring in the surgical clinic of the Royal University of Parma. S. C., æt. 17, peasant, of robust physique, well formed, no bad history. Parents always healthy. At the age of ten years he noticed a small induration about the middle of the right half of the inferior maxilla. It commenced spontaneously, and caused no pain, even after prolonged examination, and though it kept on growing, the patient had not thought that it could be removed. He entered the clinic on December 3, 1882, at which time the tumor was of very large size. The swelling commenced at the mental symphysis, extended along the whole body of the bone, and about a third of the distance up the ramus. The mass was hard, resistant, smooth, and immovable, It was so large that the patient could only open and close his jaws with great difficulty. The mucous membrane of the mouth was sound and freely movable over the tumor, but very much distended. The diagnosis of central osteo-sarcoma of the inferior maxilla was made. On Dec. 5th, Ballini's operation was performed, the bone being resected at the symphysis and disarticulated. Cicatrization proceeded normally and without a bad symptom until about the end of December, when the part began to have a suspicious look.

It was noticed at the time of the operation that the parotid gland was unnaturally firm. This firmness increased so rapidly that it was found necessary on January 11th to extirpate the right parotid, submaxillary, and some cervical glands. The patient left the clinic, cured, on February 20th.

In the same article Ceccherelli reports a case of resection of the inferior maxilla for epithelioma, the external method being used in this case also. The patient entered the Hospital on Dec. 4, 1882, and was discharged on January 11th. No recurrence up to date. In both cases the diagnosis was confirmed by microscopic examination of the tumors.—*Lo Sperimentale*, June, 1883.

NEPHRITIS FROM COMPRESSION OF THE URETERS IN CANCER OF THE UTERUS, WITH CONSECUTIVE HYPERTROPHY OF THE HEART.—It is not rare to find, says M. G. ARTAUD, at the autopsy of women dead of cancer of the uterus, either one or both ureters compressed or obliterated by the neoplasm. This compression or obliteration causes dilatation of the ureter above, distention of the pelvis and calices of the kidney and alterations of the renal substance, which vary according to the intensity or duration of the compression; and in these cases it is not rare to find in women who die in a state of extreme anæmia, a hypertrophy of the left ventricle of the heart, which has been caused by the secondary nephritis. After having studied these cases, Artaud draws the following conclusions:

1. In the course of cancer of the uterus there may be developed, from compression of the ureters, kidney lesions, of which the principal characteristics differ according to the degree and duration of the compression.

When there is but little compression, the size of the kidney is normal or slightly increased. The histological lesions consist in a nuclear infiltration about the uriniferous tubules and the glomeruli and small arteries, a hypertrophy of the glomeruli, and a dilatation of the convoluted tubes, of which the epithelium has undergone fatty degeneration. The size of the collecting tubes is normal, or nearly so, and the epithelium unaltered.

In cases of long-continued pressure, where the ureter and pelvis of the kidney are very much dilated, the kidney becomes atrophied, and the degree of atrophy is in direct proportion to the dilatation of the ureter and pelvis. The pathological lesions consist in the passage to the fibrous state of the nuclear infiltration observed in the beginning of the disorder, and in the breaking down of the straight and collecting tubes, the epithelium of which has undergone embryonic change. The glomeruli undergo either fibrous or cystic change and the convoluted tubes present the same epithelial alterations as in the first stage.

Kidney lesions produced by compression of the ureter in the course of cancer of the uterus frequently bring on hypertrophy of the heart, which is exclusively confined to the left ventricle. This hypertrophy is rarely accompanied by interstitial nephritis. This forms another variety, hitherto but little studied, of cardiac hypertrophy coming on in the course of affections of the urinary organs. — *Gaz. Méd. de Paris*, August 4, 1883.

Fusible Metal for taking Casts of Anatomical Preparations.—Dr. J. S. Mixter recently read a paper on this subject before the Boston Society for Medical Observation. The methods used by Hyrtl for corrosion preparations do not answer well in our climate, as they are apt to melt in the hot summer weather. Henle used metal for casts of the ear, and Sands for those of the urethra, but no use seems to have been made of such metal for the finer injections of the bloodvessels. The compound used is known as Wood's metal, and consists of bismuth, seven parts; lead, four; tin, two; and cadmium, one. This will melt at a temperature of from 140° F. to 160° F. It should be melted under water which has been previously boiled, in order to prevent the rapid oxidization which takes place when it is heated in the air. After having heated the organ to be injected to 140° F. the metal is forced in by means of a syringe, and the part left to cool for some time, for when near the melting point it becomes quite brittle, but when cooler it can be handled quite safely. After having injected and cooled the organ it is immersed in a warm concentrated solution of caustic potash for some two hours, when the tissues become softened, and can be washed away with cold water.

Very beautiful preparations were shown of injections of the vein and artery of a human kidney, of the fœtal circulation of a human child at birth injected through the umbilical cord, also preparations of the lungs of a sheep and a cat injected through the trachea, and specimens from the liver and kidney of animals. Dr. Mixter has also made some injections of bone by placing the specimen, immersed in the liquid metal, under the bell of an air-pump; the air was then exhausted, withdrawing the air also from the interior of the bone; on readmitting the air to the bell the metal was forced into the finer bony openings, and a cast was thus obtained. It was often necessary to soak the bone for a week in the strong potash solution or even to use strong sulphuric acid.—*Boston Med. and Surg. Journal*, August 16, 1883.

Toxic Effects of Albuminous Urine.—Recently, M. Doléris has made a second communication to the Société de Biologie on the toxic properties of albuminous urine collected from pregnant women, and containing microbial elements. Inoculation of the culture liquid obtained by using these elements has produced the same microbes in the blood of inoculated animals, with convulsive seizures before death.—*Gaz. Hebdom.*, July 27, 1883.

A New Method of Detecting the Tubercle-bacillus.—Dr. C. Theodore Williams has lately adopted a modification somewhat resembling Rindfleisch and Chill's, which still further simplifies and shortens the process. The cover-glass with the dried sputum thereon is floated in a few drops of magenta aniline in a watch-glass, and heated over a flame till vapor is seen to rise from the surface. The watch-glass is then removed and allowed to cool for two or three minutes, the cover-glass is afterwards treated successively with nitric acid (1 in 4), with distilled water and a weak solution of alcohol. It is dried and mounted in Canada balsam, the whole process not exceeding eight minutes. —*The Lancet*, July 28, 1883.

Sanitary Value of the Electric Light.—Prof. Max Pettenkoffer has recently given a detailed opinion of the electric light in theatres, in which he draws the following conclusions: 1. The electric light hinders, to a great extent, the overheating of the air in the theatre. 2. Of course, it does not render ventilation of the theatre superfluous, but affords in itself a more thorough means of ventilation than gaslights, which contaminate the air of the room by the heat and products of combustion, both of which are avoided by using the electric light.—*Wien. Med. Presse.*, July 29, 1883.

Antisyphilitic Properties of Cascara Amarga, Baroba, and Berberis Aquifolium.—For the past four years Dr. Frohling, of Mexico, has used cascara amarga, the bark of a tree of Honduras of the genus picramina as an antisyphilitic. The fluid extract is given in doses of gtt. xl–l to an adult in secondary syphilis. The symptoms quickly disappear, and the tonic action of the remedy is striking. In a case of specific iritis, Reuling has seen a manifest amelioration within three days—the dose being gtt. xl of the fluid extract three times a day. The instillations of atropia were stopped and cascara amarga used alone.

The leaves of the Brazilian baroba, the extract of which is officinal in France, have been used by C. Weber, of Leipzig, and by Edson, in obstinate forms of secondary syphilis, gtt. xv–ʒj being given in a day. It is a valuable antisyphilitic tonic and alterative.

According to Dr. Baird, of Tennessee, the berberis aquifolium (Oregon grape root), is a valuable remedy in secondary syphilis. He has prescribed it in two cases in syrup or a solution containing ʒxv of iodide of potassium—dose, a dessertspoonful in coffee three times a day.—*L'Abeille Méd.*, Aug. 6, 1883.

Dilatation of the Cervix in Hysterical Opisthotonos.—A young woman was recently brought to von Nussbaum's clinic, who one year before had had the operation of slitting the cervix performed on account of amenorrhœa and hysterical cramps. The operation had given relief, but was not permanent.

The cervix felt hard and cartilaginous, and the os was closed. The cramps had returned and were of the true opisthotonic type. Von Nussbaum repeated the slitting, and inserted his index finger into the uterine cavity; he then thoroughly cauterized the lips of the wound with Paquelin's thermocautery. The operator hopes for the best results from this treatment, and so far the cramps have not returned.—*Allgem. Wien. Med. Zeitung*, July 31, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, AUGUST 25, 1883.

THE RESULTS OF THE QUININE PILL ANALYSES.

THE profession has just been favored with another analysis of quinine pills which fully confirms the prior results of THE MEDICAL NEWS Commission. Last April, when *The Pharmacist* published Prof. Diehl's analysis, it offered to produce the remaining pills of the packages from which the samples were taken, if the manufacturers so desired, for another analysis under their supervision. This offer was not accepted by any of them, with the single exception of Messrs. McKesson and Robbins, "seemingly on the ground," according to *The Pharmacist*, "that it was forgotten by the masses, and, therefore, it was better to let it remain unsettled than to again try an investigation."

After the successive declinations of Prof. Diehl, Prof. Prescott, Mr. Charles Rice, Dr. Squibb, and Dr. Mott, Messrs. McKesson & Robbins finally secured the services of Mr. Wm. Habirshaw, who is one of the New York Custom House analysts of cinchona bark, as an expert to witness the analysis to be made by Dr. Edward Polenske, the chemist of Messrs. McKesson & Robbins. The analysis was made in New York by Dr. Polenske in the presence of Mr. Habirshaw and Prof. Austin as chemists, Mr. Cowdrey, the editor of *The Pharmacist*, and two representatives of the firm of McKesson & Robbins. The herapathite test, as advanced by Prof. Diehl, was used, it being modified only "where it was considered that Prof. Diehl had erred." The results are given in *The Pharmacist* for August.

Four samples were analyzed. To test the correctness of the method, the accuracy of calculation, and the expertness of the chemists in manipulation, Mr. Cowdrey had two samples of pills carefully made in Chicago with known quantities of Powers & Weightman's sulphate of quinine, and then gelatine-coated. No. 1 consisted of one hundred pills made from two hundred grains of sulphate of quinine. No. 2 consisted of one hundred pills made from two hundred grains of a mixture of sulphate of quinine 95 per cent., quinidia sulphate 2½ per cent., and cinchonidia sulphate 2½ per cent. No. 3 was the remainder of the original sample analyzed by Prof. Diehl; and No. 4 was some two-grain quinine pills of *recent manufacture* taken from McKesson & Robbins' stock-room. Sample No. 3, upon analysis not representing the amount of quinine that Messrs. McKesson & Robbins thought it should, and "there being a question if the alkaloid bearing ether had not inadvertently been lost by the too rapid boiling of the ether while on the water-bath," it was decided on the following day to make from the same sample another analysis, which is numbered 5.

The results per two-grain pill are given in grains in the following table:

No. of Sample.	Total Quinine Sulphate, $8H_2O$.	Total Alkaloid as Sulphates, $8H_2O$	Per cent. of Foreign Alkaloid.	Deficiency of Total Alkaloids.	Deficiency of Quinine Sulphate.
1	1.992	2.090	.46		.008
2	1.893	2.052	.77		.107
3	1.782	1.869	.47	.131	.218
4	2.036	2.083	.22		
5		1.963			

No. 5 shows a larger amount than No. 3 of total sulphate alkaloids, although still deficient in weight. For some reason, the amount of sulphate of quinine present in it does not appear to have been calculated.

It will be observed that in these new analyses the manufacturers have the benefit of the increased weight resulting from calculating the sulphates as containing eight equivalents of water of crystallization, which are allowed by the *U. S. Pharmacopœia*, although its standard officinal formula gives seven equivalents, and the calculations of THE MEDICAL NEWS analysis were made on this basis. In commenting on this point, *The Pharmacist* says: "It is plainly evident that eight molecules of water are more than a fair allowance for water of crystallization, as it is evident that the bottle of Powers and Weightman quinine did not contain quinine with over seven molecules of water. The figuring of results on the basis of eight molecules increased the amount of alkaloid in 1 and 2 beyond the amount actually present; but if the *Pharmacopœia* allows eight molecules of water of crystallization, we can hardly object to the manufacturers claiming the utmost limit of the *Pharmacopœia*, even though the quinine of commerce contains less than that amount."

The foregoing results, we suppose, are accepted as correct by Messrs. McKesson and Robbins, since they were obtained by their own chemist. They are certainly very satisfactory to us, since they closely agree with our own results, and are strongly confirmatory of the accuracy and correctness of our analysis, which gave for the McKesson & Robbins' two-grain pill 1.76 gr. calculated with seven equivalents of water of crystallization.

IT is with great satisfaction, too, that we note the beneficial results to both the profession and the public which have followed the publication of THE MEDICAL NEWS analysis. It was to be anticipated that the houses whose products were found to be deficient would carefully investigate every point in their pill manufacture, and even revise their working formulæ, if found necessary to bring their products fully up to the standard which is claimed for them. In the case of Messrs. McKesson & Robbins, this appears to have been done, and it is with very great pleasure that we note that a recently manufactured sample taken from their store-room was shown by the analysis just made to contain the full weight of sulphate of quinine, and we have no doubt that if the pills of recent date of other manufacturers had also been examined, a like result would have been found. Thus the profession and the public, as well as the manufacturers, will be the gainers by the greater care which is now being bestowed upon the character of the laboratory-products of our large manufacturing pharmaceutists.

WHEN, last December, THE MEDICAL NEWS published the results of its analysis of certain leading brands of quinine pills, we observed, without any special surprise, that little, if any, notice was taken by our contemporaries of the rather startling results, in spite of the importance to the profession and the public of the fact that this dominant pharmaceutical product seemed to be very largely manufactured of short weight.

We say that we were not surprised, for we were advised that some manufacturing houses, whose wares had failed to come up to the standard, and whose advertising patronage was large and influential, had issued requests (perhaps we might rather say commands) that the investigations of THE NEWS Commission should be sneered at or suppressed, under threat of withdrawal of advertising. Our information came from sources which we could not discredit, and though we were unable to obtain copies of the letters in question, we could not disbelieve their existence, humiliating though the fact might be to professional journalism.

It seems that the able and independent *Pharmacist and Chemist*, published by the Chicago College of Pharmacy, was thus approached. So far from granting the request, *The Pharmacist* was led to repeat and carry out the investigations of THE NEWS Commission, with the result, as our readers know, of fully confirming them. *The Pharmacist* now follows this up, by giving in its August number the following interesting extracts from letters which it had received demanding the suppression and contradiction of the article in THE NEWS:

"The republishing of this article will do us great injury; therefore, being liberal advertisers with your journal, we have to ask that you will withhold its publication."

Another writes:

"This matter is of great importance to us, and an opportunity offers itself to you to render us and myself a favor which we will be most glad to reciprocate when occasion offers. Can you not then, taking the comments which we lay before you, come out and say something to restore the confidence of any of your readers which may have been disturbed by the absurd article in THE NEWS?"

And still another writes:

"We feel that the time has come when we must decide to withdraw our advertisements from all journals that take issue against our interests. The recent action of THE MEDICAL NEWS is a case in point, and we ask you if, in justice to ourselves, it is not right that we should expect that you will condemn the analysis as published by them?"

While thanking *The Pharmacist* for the manly and independent position which it has assumed in this matter, we leave to our readers to discuss the problem as to whether the primary allegiance due by a medical journal is to its subscribers or to its advertisers.

NEW TESTS FOR SUGAR—PICRIC ACID.

WHILE the methods now in use for the qualitative testing of albumen seem to be as satisfactory as one may desire, the same cannot be said of the tests for sugar in urine. What, with the reducing power over the oxide of copper which is possessed by uric acid, and to a less degree by other constituents of urine, and the action of creatinin and other substances in preventing glucose, even if present, from reducing the oxide of copper, it is evident that the copper tests which are at once the most delicate and convenient, are far from satisfactory.

In the face of these facts all reagents which are superior to existing ones are welcome. Unfortunately, not all tests which are claimed to be superior by their suggesters bear the test of trial by others. Careful examination has satisfied us that two or three of those recently brought forward may safely be recommended to the profession as at least likely to be useful as comparative tests where doubt exists.

One of these, recently suggested by Dr. George Johnson (*Lancet*, March 17, 1883), is *picric* acid, the sensitiveness of which as a test for albumen has not long ago been alluded to in these columns. Picric acid is reduced to deep-red picramic acid by glucose when boiled with potash. To apply the test, a drachm of urine, a half drachm of liquor potassæ, and ten minims of a saturated solution of picric acid, the whole being diluted to three drachms by distilled water, are heated to the boiling-point and kept boiling for sixty seconds. If sugar is present, the fluid acquires a beautiful deep-red color, the depth of color being proportionate to the amount of sugar present. We have found half the quantities suggested by Dr. Johnson more convenient to work with, at least for qualitative testing.

For quantitative testing a standard solution is made by boiling together, for sixty seconds, a mixture containing one drachm of a solution of grape sugar containing one grain to the ounce, half a drachm of liquor potassæ, and ten minims of a saturated solution of picric acid, the whole being increased to three drachms with distilled water. The resulting color corresponds to an amount of sugar equal to one-quarter of a grain to the ounce.

For the purposes of a permanent standard, this color is exactly imitated by dissolving acetate of iron with excess of acetic acid. The color thus produced will then also correspond to that produced by a solution containing one-quarter of a grain of sugar to the ounce, when treated as above.

The above-named proportions of the suspected urine, liquor potassæ, and saturated solution of picric acid, the whole diluted as before to three drachms, are then boiled for sixty seconds and the resulting fluid compared with a column of the standard solution in a test-tube of equal diameter. When the color of the boiled fluid is deeper than that of the standard, it is diluted until they agree in tint. With these data the quantity of sugar may be evidently calculated.

If the urine contains more than one grain to the ounce, the quantity of the picric acid solution must be increased ten minims per grain; and if the urine contains more than sixty grains to the ounce, it must first be diluted by distilled water to a definite proportion.

This test is said to be quite unaffected by albumen, but a turbidity occurring in the process of testing, due to phosphates, must be filtered out. Dr. Johnson found identical results in analyzing the same specimens by this method, and by Dr. Pavy's ammonio-cupric solution. We have tried it in qualitative testing and obtained distinctive reactions with urines containing but small quantities of sugar, but are not prepared to speak authoritatively of its relative delicacy. As to quantitative testing, we should infer that it would be only in the hands of experienced analysts that gradations of color should be relied upon in determining quantities.

In future issues we will describe other recently suggested tests for sugar.

COLD DRINKS IN HOT WEATHER.

VERY vague notions exist in the popular mind as to the use of cold drinks and ices when one is very warm and perspiring. There is a vague impression that they are harmful, but few know how or why. The fact is that the use of iced water as a drink, in moderate quantities at a time, even if often repeated, is not harmful, but advantageous to the over-heated and perspiring individual. By their use, the temperature of the blood and body is lowered, and the loss of water by perspiration is made up — two important safeguards against the effects of overheating.

But the ingestion of large amounts of iced water by the overheated may be harmful, and in more ways than one. In the first place, among the most frequent but less serious consequences of the use of such amounts of cold water is the result of its use at meals, when the deluging the stomach with cold water lowers its temperature below that at which digestion is best accomplished, and this important function stops or is retarded until the proper temperature is regained. Dyspepsias and diarrhœas and possibly cholera morbus may be the consequence. The same results may ensue from the use of ice-cream and water-ices, and these truths apply, of course, to all seasons; it is simply that the abuse is more apt to occur in hot weather. We have more than once seen little children who have had attacks of vomiting after concluding a full meal supplemented by the free use of ice-cream, and we recall one instance in which convulsions supervened.

Another more serious consequence of the ingestion of large amounts of ice-cold water, and one which can perhaps only occur with an empty stomach, is sudden death. This, although a rare event, is still sufficiently frequent to make a word of precaution necessary with regard to its cause. This happens, as already intimated, when large amounts of ice-cold water are drunk on an empty stomach by an overheated person. Its action is doubtless through the nervous system. The nervous supply of the stomach is, by the pneumogastric and branches of the sympathetic, derived from the splanchnics and solar plexus. The former is the motor nerve, whose operations are chiefly regulated by the central nervous system, and the latter may be termed the sensory nerves. The accident may be explained by supposing a sudden shock upon the terminal filaments of the sympathetic nerve carried to the solar plexus, and thence to the medulla oblongata; whence an inhibitory impulse is reflected along the vagi to the heart and stops its beating. The effect is analogous to that daily produced by the experimental physiologist by means of an induction shock applied at any part of the course of either vagus.

It is well known that when atropine is injected into the blood of animals experimented upon, the strongest induction shocks fail to produce this inhibition. Might not some practical use be made of this fact in cases of sudden heart-stoppage from this or other cause?

Another method of deleterious operation of the ingestion of large quantities of water, which applies of course to water at any temperature, has been suggested. It is that in the thickened state of the blood which succeeds the rapid transpiration of the water of the blood in hot weather, a condition favorable to the rapid absorption of large amounts of ingested fluid is produced. The effect of the addition of such a large amount of water to the blood is to promote a solution of the red-blood corpuscles—a hæmoglobinæmia—which, of course, if extensive, must be incompatible with life. But we have grave doubts of the operation of such a cause as this. However rapid the osmosis, it must cease as soon as a certain degree of dilution of the blood is reached.

A very reasonable question is, What quantities, then, of ice-cold drink may be taken with impunity by a person overheated and perspiring freely? We answer that it is not so much a matter of quantity as rapidity. If the cold water is introduced slowly, a few mouthfuls, or even a half tumblerful, at a time, followed by the same quantity in a couple of minutes, we do not think it likely that any serious results will follow. It is our impatience in this, as in many other things, which leads us into danger, and if the proper precautions are observed, the American custom of taking iced drinks may not only be a harmless, but actually a wholesome as well as an agreeable luxury.

PRELIMINARY TREATMENT vs. QUININE.

In no part of the world has the change of opinion, in regard to the antiphlogistic treatment, been so complete and radical as in India. In an interesting paper on the subject of the treatment of remittent fever as it occurs in India, Dr. Norman Chevers compares the old practice of large and repeated bleedings, and mercury given to ptyalism, with the modern method of quinine in full doses. It is hardly necessary to say that the latter is now the general practice in India as elsewhere.

There is, nevertheless, a practical question here in regard to the necessity of some preliminary treatment as a preparation for the administration of quinine. There is a belief, shared in by a good many excellent practitioners, that the curative effect of quinine is enhanced by such preparatory treatment. It is held that quinine is not properly absorbed when the tongue is heavily coated, the conjunctivæ yellow, the stomach in a catarrhal state, and the portal system congested, and that these conditions must be removed by the administration of mercurial purgatives. As these apparent complications are really the morbid complexus, and have the same significance as the fever, it would seem probable that the remedy effective against one set of symptoms ought to be equally so against the other. Experience confirms this, for if quinine be given suitably, with the disappearance of the fever the accompanying disturbances cease also.

It is important, however, to separate those symptoms due to the malarial infection from complications properly speaking. Complications determined by the systemic disturbance, and not a necessary part of the malarial disease, require appropriate treatment. The question in any case will be settled by the application of this rule. As an illustration of this we may take the condition of intense gastroenteric irritability, which, preventing the absorption of quinine, requires well-directed preliminary treatment.

TUBERCLE-BACILLI IN DISCHARGES FROM THE EAR.

The most recent seat of demonstration of the presence of the bacilli of tuberculosis appears to be the middle ear. Dr. Eschle in the *Deutsche med. Wochenschr.* for July 25th, reports two cases in which the discharge from suppurative disease of the middle ear contained bacilli. In one there was concurrent advanced tuberculosis of the lung. It is interesting to note that the discharge, for several days, presented the appearance of "blue pus," said to have been observed but twice by Politzer in his experience with discharges of the ear.

In the second case, that of a boy, although there had been scarlatina, nephritis, diphtheritis and suppurating lymphatic glands, physical exploration of the chest gave negative results, and the perforation of the tympanum subsequently closed. Myringitis and otitis externa continued, and bacilli continued to be found in the discharge.

The bearing of these observations on the possibility of the existence of tuberculosis of the middle ear—supposing a necessary relation of bacilli to tubercle—is evident.

REVIEWS.

A System of Human Anatomy, Including its Medical and Surgical Relations. By Harrison Allen, M.D. Section IV. Arteries, Veins, and Lymphatics. 4to. pp. iv. 335–438. Philadelphia: Henry C. Lea's Son & Co., 1883.

We can congratulate its accomplished author on the steady progress of this book—a genuine storehouse of anatomical knowledge and of its applications to medicine and surgery. No other work with which we are acquainted exactly fills its place. Its descriptions are none too long, and its remarks on the bearing of the anatomical facts on the numerous pathological conditions, whether frequent or rare, are of the utmost value to the practitioner. Many a case involved in more or less obscurity will be cleared up to him if he will refer to the observations on the variations, and the clinical relations of the structures involved. Especially is this true in the interesting notes on the zoölogical analogies to variations in human anatomy and on the development of the fœtus. In noticing the previous sections, we have so frankly and so forcibly expressed our opinion of the value of the book, that it would be but iteration to say it anew of each part.

But, as with the Seven Churches of Asia, we must say of every part "Nevertheless I have somewhat against thee"—errors to be corrected in the second edition, which we doubt not will soon be demanded.

The plates are greatly improved over the other sections. The color printing is admirably done, and the finish is better. Still many of the names appear indistinct, and there are faults, some of which are simply blemishes, but others are serious errors. Thus, in Pl. lxi. Pneumogastric, in Pl. lxx. Tendo Achillis, and in Pl. lxxiv. Hæmorrhoidal, are all misspelled, and in Pl. lxx. "Interossea Art." should be either "Interosseous Art." if English, or "Art. Interosseæ" if Latin.

But anatomical errors are more serious, and we were quite startled, in Pl. lxi. Fig. 2, to find a subject showing both common carotid arteries on the left side of the neck, and a branch from the right common carotid just above the clavicle, the distribution of which is left to the imagination, as it well may be. In Pl. lxx. the number of terminal slips, both of the extensor longus and extensor brevis digitorum, is inexact; and no one, we are sure, can trace the connection of the belly and the tendon of the extensor proprius pollicis. Plate lxxvi. Fig. 2, makes the internal carotid artery spring from the aorta, and shortens and displaces the internal jugular vein in a way that cannot be accounted for by the pose of the head and neck. The student will often be puzzled to recognize unlabelled structures, as in Pl. lxx. the slips of the extensor brevis. Fig. 84 gives us a very long, unlabelled superior intercostal vein, or azygos minor, as it is often termed, in distinction from the hemiazygos (though usage is not very uniform as to these names), while Pl. lxi. makes the hemiazygos empty very high up and into the cava, and not into the azygos major, as in Fig. 84; and in Pl. lxxi. the external jugular is not labelled, though the anterior is.

Of the text, we have little to say but praise. On p. 402, Dr. Kelley's recent paper on the double femoral artery should surely have been referred to, or the account in Henle's *Anatomy*, rather than Sir Charles Bell's single case, in 1826, and Mr. Houston's, in 1827. On p. 411, the interosseous arteries are termed digital; the definite, fixed order of relation of the posterior tibial artery and nerve and the accompanying tendons behind the inner malleolus (p. 408) is not clearly stated; and on p. 398 it is said that, when the obturator artery skirts Gimbernat's ligament, it "would in this position, of course, be wounded in operating for femoral hernia," instead of "it may be wounded."

But, *per contra*, no one unless he has made a book, especially one with many and intricate plates, can possibly know how hard it is not to make some errors. Happiest he who makes the fewest.

Abdominal Hernia. By Rushton Parker, B.S., F.R.C.S., etc. 8vo. pp. 56. Liverpool: Adam Holden, 1883.

Three ideas seem to dominate this production, viz., it is not good to feed patients with strangulated hernia; it is not the strangulation of omentum which proves serious in so-called omental hernia; it is wise to attempt a radical cure in operations of herniotomy, by ligating the peritoneal layer of the hernial covering close to the abdominal opening, after reduction of its contents.

If there be, in the way these ideas are presented, any merit which outweighs the disadvantages of the author's style, we have not discovered it.

The monograph is unsystematic, incomplete, tiresome to read, and unremunerative when read.

SOCIETY PROCEEDINGS.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, Thursday Evening, June 28.

The President, James Tyson, M.D., in the Chair.

Dr. J. S. Musser presented

A SPECIMEN OF RENAL CALCULUS, OXALATE OF LIME,

with the following history:

R. K., æt. 32, a stone-cutter, residing one year in Philadelphia, applied to me for treatment June 5, bringing with him a sample of his urine. It was bloody, and had been voided without pain during the twenty-four hours prior to this visit. Three months ago, without any cause, he was seized with pain in the left loin. The pain increased in severity, kept him from work, caused faintness, but no nausea or vomiting; did not radiate in any direction, save transversely to a slight extent; lasted three days, and was not followed by hemorrhage. In the intervening three months he was in good health. A jar of the body or any movement did not increase the pain. It may be noted, but is rather irrelevant, that for ten or more years he has always had a weak back, becoming painful when stooping.

Twelve hours after the consultation this same localized pain recurred, and continued for twenty-four hours. Suddenly it was relieved, and the subsequent urinary discharges were clear. In three days, he had a return of the pain and hemorrhage simultaneously. The pain increased in severity, and at the height of the paroxysm extended to the testicles and the head of the penis. The paroxysm was relieved by the passage, of the calculus I show you, by the urethra. The passage of the stone through the ureter was characterized by the most agonizing pain and frequent attempts to urinate. Microscopical examination of the first sample of urine showed the red color to be due to blood. A similar examination of his clear urine, as well as the bloody, proved the presence of urate of soda and crystals of the phosphates. The urine was acid. The diagnosis of renal calculus was not difficult, but the microscopical appearance of the urine led me to infer that the stone was composed of uric acid. With such ideas, the patient was put on alkaline treatment. The sequelæ proved that the solvent effect of such treatment was of no avail, save from the diuretic action of the drugs. Morphia was given to relieve pain.

A portion only of the stone was received, an angular portion having been broken off by the patient. The portion weighs sixty-six grammes. The exterior is tuberculated; the interior dark, in color bluish; the exterior laminæ light-brown. It is exceedingly hard. Chemical examination was made by Dr. Leffman, who reported it to be an oxalate of lime calculus.

HÆMATOMA IN THE UPPER PORTION OF THE MEDIASTINUM PRODUCING DEATH BY SUFFOCATION.

DR. J. T. ESKRIDGE said that he obtained the specimen from a colored man, porter, aged thirty-two years. He had led an irregular life, but it was not positive that he had ever contracted syphilis. During the past winter he suffered from a severe cold on the chest, and was told by his physician that his heart was inflamed. With the exception of a slight cough, unattended by any difficulty in breathing, he had considered himself in excellent health. On June 10, 1883, after carrying a heavy trunk on his shoulder from the first to the fourth floor of a hotel, at Cape May, he was seized immediately with great difficulty in breathing, and was compelled to seek the open window to prevent suffocation. During the next two days, while still remaining at the sea-shore, he suffered from several attacks of shortness of breath, each lasting from several minutes to an hour or more.

He was admitted to the Hospital of the Jefferson Medical College on the evening of June 12, about sixty hours after the occurrence of the accident. On admission, his breathing was so labored that he was unable to speak. He was gasping for breath, and bathed in profuse cold perspiration. Respiration 36, with greatly prolonged expiration; pulse 100; temperature 99.7°. Inhalations of amyl nitrite, and the hypodermic use of morphia and brandy seemed to give relief. The attack lasted about twenty-five minutes. He slept well during the night, and was tolerably comfortable until 5 P.M. the next day, when he had another paroxysm, which was promptly checked by amyl nitrite, morphia, and dry cups to the chest.

June 14, A.M.—Dr. Eskridge saw him for the first time. The patient was breathing quietly, and said that he felt comfortable. Pulse and temperature were nearly normal; urine contained neither albumen nor sugar; no cardiac murmur was detected; lungs were hyperresonant at their apices. Loud, moist bronchial râles were present throughout both lungs. In view of the man's former freedom from attacks of dyspnœa, he thought that he detected nothing capable of giving rise to so great interference with respiration. The next two days no dyspnœic attacks occurred, and he seemed to be doing well.

17th.—His breathing was distressing for several hours. Nothing seemed to afford much relief.

18th.—Severe asthmatic breathing came on at 6 A.M., and lasted in its worst form about six hours. Chloral hydrate gave some relief. After that paroxysm his breathing did not again become quiet. He died, exhausted, at 7 P.M. the next day. With the exception of occasional headache, he did not complain of pain at any time.

Sectio cadaveris was made by Dr. Parrott, the medical resident, the pathologist of the hospital and Dr. Eskridge being absent from the city at the time.

Thorax—pericardial sac was completely obliterated by old, firm adhesions between the pericardium and heart. The heart was rather fat, and both ventricles were relaxed and contained considerable dark fluid blood. Valves nearly normal. Both pleuræ were adherent to the upper portion of the pericardium, and the left pleura was everywhere adherent to the lung. Both lungs were emphysematous at their apices, and considerable lobular emphysema existed. Bronchial tubes were congested and contained considerable mucus. A semi-solid, or rather soft oblong body, about two inches long, by one and a half wide, was found lying upon the lower anterior surface of the trachea, embedded in connective tissue, and firmly held by old adhesions. It occupied a position just above and behind the transverse portion of the arch of the thoracic aorta. Three of the rings of the trachea in the position where the greatest pressure was exerted by the semi-solid mass presented a dark color, and one of the spaces between the discolored tracheal rings was nearly ulcerated through from the effects of pressure. On cutting into the tumor, it was found to consist of blood, more or less clotted. The calibre of the trachea was greatly lessened at the seat of hemorrhage. No ruptured bloodvessels were found. No disease was observed in any of the arteries. Abdominal organs were nearly healthy in appearance.

DR. ESKRIDGE, in his remarks on the case, said that numerous cases of rupture of the aorta, or of smaller bloodvessels, into the trachea, bronchi, œsophagus, or mediastinum, were on record, but in all of them, so far as his knowledge went, death resulted directly from loss of blood. The peculiarity of the case, of which he had given a description, was the formation of a hæmatoma in the mediastinum. In hemorrhages into that space, the blood usually gravitated to the lower portion of the chest, and the patient soon died from loss of blood. In the case he presented, however, on account of extensive old and firm adhesions of pleural and pericardial connective tissue, and everything else in the upper portion of the mediastinum, a hemorrhage in that situation must necessarily have been circumscribed, and could have taken place only gradually by dissecting up the adhesions. He thought that the condition of the parts that prevented an extensive hemorrhage predisposed the smaller bloodvessels, especially the veins, of that locality to rupture. In view of the extensive alterations, by means of general adhesions, that had taken place at the seat of hemorrhage, it was not surprising that rupture of a bloodvessel should have occurred, when the parts in the anterior region of the neck and upper portion of the chest were suddenly put upon the stretch as occurred in the act of raising a heavy trunk from the floor and placing it upon the shoulder. From the specimen, as he obtained it, he was unable to say whether the hemorrhage had occurred from a rupture of the aorta or one of the smaller vessels, or from the bursting of a very small vessel that had become aneurismal. The tearing across of small veins would have been sufficient to give rise to the extravasated blood.

DR. NANCREDE presented a

CONGENITAL FATTY TUMOR BENEATH OCCIPITO-FRONTAL MUSCLE.

The tumor was simply presented on account of the rarity of such growths of *fœtal origin*. The patient was a child aged sixteen months. The growth was noticed at three weeks, and in consequence must have been of fœtal origin, as it then was of the size of a bean. It presented none of the symptoms of a fatty tumor, except a faint lobulation, the skin moving freely over it, and presenting none of the dimpling so common in lipomata. Its site was peculiar for a dermoid cyst, viz., over the right occipito-parietal region, yet its resemblance was so close, that by exclusion it was considered to be a congenital cyst. Upon removal it was seen to be distinctly beneath the aponeurosis of the occipito-frontal muscle. Microscopic sections kindly made with the freezing microtome by Dr. N. G. MacConard showed that the growth was a pure lipoma.

Dr. Nancrede also presented an

ADENOMATOUS GROWTH APPARENTLY RECURRENT: IN REALITY AN OUTLYING PORTION OF THE MAMMA NOT REMOVED AT A PREVIOUS OPERATION.

The above title really gives the essential points in the history of a patient, aged twenty-three years, upon whom two operations had been performed for a supposed fibroma (adeno-fibroma?) of the breast, which recurred after partial removal of the breast; the whole organ was supposed to have been then removed by another surgeon. Dr. Nancrede had opposed all operations at first, considering the breast was really not the seat of anything beyond a local induration after injury. He had subsequently removed the third growth, which, from its history and microscopic appearances, he was satisfied was the result of the irritating drag of the badly placed cicatrix on a small portion of breast tissue left at the second operation. The clinical lesson taught by this case was clear, viz., the freest possible removal of mammary growths.

Dr. Henry presented specimens from a

CASE OF ACUTE PHOSPHOROUS POISONING,

consisting of stomach, liver, kidneys, heart, and spleen. The phosphorus was taken with suicidal intent, during the night of May 7th, and was obtained by soaking the heads of a box of matches in water. Fifteen minutes after swallowing the solution, the patient, a male German, æt. 22, experienced a burning sensation in the stomach, which, in the course of a few hours (about six), steadily increased until the pain became excruciating. Copious and repeated attacks of vomiting then ensued, and followed every attempt to allay thirst, which was excessive. On the 8th there was a very loose discharge from the bowels.

The patient was admitted to the hospital on the tenth. His skin was sallow and dark, but not then icteric in hue. There was tenderness over the liver, and the line of liver-dulness was slightly increased. Severe pain in the abdomen was complained of, and this pain had continued with occasional intermissions since the 8th. The pulse was full and strong, 84 per minute. The temperature was 100°. The urine contained considerable albumen, but no casts, nor other abnormal ingredient. I extract the following from notes taken by the resident physician, Dr. James S. Carpenter.

May 11.—No pain. Pulse 100, temperature $98\frac{3}{5}^\circ$. Patient refuses food, but craves acid drinks.

12th—.Vomited once, but phosphorus not tasted by the patient as heretofore. Pulse 108, and weaker. Temperature, which was 101° on the evening of the 11th, now $98\frac{3}{5}^\circ$. Decided icterus. Thirst continues.

13th.—Jaundice increased; tongue dry and brown; red at edges; abdominal wall covered with numerous petechial spots. Pulse 126, temperature 100°.

14th.—Intense jaundice; one clay-colored stool; pulse very weak—132; temperature $98\frac{1}{2}^\circ$; extremities cold; bladder relieved by catheter; forty-eight ounces removed. The urine contained bile-pigment in large amount, and had a strong odor of phosphorus. The man died at 11.40 A. M., one week, less fourteen hours, after taking the poison. As the patient was not admitted until the third day after he had swallowed the phosphorus, the treatment was directed towards relieving pain, and retaining the strength as far as possible.

At the autopsy, which was made very soon after death, the stomach was found filled with a grumous, bloody fluid, but the gastric mucous membrane was quite pale and free from erosion or any sign of inflammation. The folds of mucous membrane upon its surface were, however, unusually prominent. The liver weighed three pounds fourteen ounces. The anterior border of right lobe and the parts adjacent to the gall-bladder were yellow-mottled. Streaks of this yellow coloration extended along the borders of the fissures on the under surface. In parts, these streaks were an inch in width. The bulk of the liver was normal in appearance; gall-bladder was empty; heart rigid in systole; its valves healthy; slight pericardial effusions.

Lungs—some old pleuritic adhesions and emphysematous vesicles at both apices.

Spleen and kidneys apparently healthy; blood fluid. A microscopical examination of the liver will be made and reported upon at a future meeting.

Dr. J. H. Musser presented for Dr. R. M. Givin the specimens from a case of

CARCINOMA (SCIRRHUS) OF THE BREAST,

with the following history: In November, 1882, Miss ——, a lady, of good circumstances, with a hereditary tendency to carcinoma and scrofulosis from the mother, noticed, at the upper portion of her breast, a small, extremely tender lump, the size of a hickory nut. The nodule increased in size, and on the day of removal—February 17, 1883—was as large as a duck's egg, in the first position mentioned. Neither at that time nor at any other time was the nipple either diseased or retracted, or the mamma discolored. The breast had never been injured; the lymphatics were not involved; the general health and nutrition were good.

The operation was performed on the above date by Dr. Givin on account of severe paroxysmal pain. So severe was this symptom that a slight opium habit developed. The wound healed nicely: there has been no return of the disease (May 20).

Examination of a section of the hard mass in the gland demonstrated it to be a scirrhus.

Dr. G. De Schweinitz presented a

TUMOR OF THE SCIATIC NERVE,

taken from an inmate of the University Hospital, who gives the following history:

On June 16, 1864, owing to a gunshot wound of the right thigh, he sustained an amputation of that member at the junction of the middle with its lower third. The flaps sloughed, and a few weeks later a reamputation became necessary. This stump healed, but was somewhat conical in shape, and was never comfortable from the very beginning, being subject to frequent attacks of severe neuralgic pain. Within a year from the date of the amputation, a small lump, tender to the touch, was noted, situated posteriorly and a little to the outer side of the stump. The pains now became more severe and more frequent, and were of a "jumping" character, to use the patient's own language. The tumor increased slowly in size, until three years ago, when its growth became more rapid, and at the same time the painful nature of the affection more pronounced, until lately the suffering was well-nigh unbearable. Finally the growth assumed the size which you see it now presents, and on the 12th of last month, Dr. Ashhurst removed it, since which time the patient has been free from all pain, except that which naturally accompanied the healing of his wound.

The growth is an irregularly shaped mass, about the size of a small hen's egg, having an external envelope of adipose tissue, loosely held together by connective tissue. On section, the interior is seen to be a somewhat elastic, rather dense-looking growth of whitish color, over which pass a few yellowish fibres, probably strands of the sciatic nerve. Microscopic examination of the true tumor mass shows an entire absence of any nervous elements, a section exhibiting fat cells, fibrous tissue, some spindle cells, and numerous free nuclei near the enlarged and dilated bloodvessels. The tumor would, of course, be classed clinically as a neuroma, following amputation, while in truth its pathological nature is that of a fibroma. It is interesting that a growth causing so much pain should be without any demonstrable nervous endowment; and surgically it is further worthy of note, because its removal was attended with immediate and probably permanent relief to the patient, a desired result which is by no means always obtained by the excision of these growths.

THE BACILLUS TUBERCULOSIS.

DR. LAURISON, by invitation, made some remarks upon the bacillus tuberculosis, and exhibited a number of specimens. He said that he did not employ nitric acid in preparing his specimens, as it seemed in many cases to bleach out all the bacilli from the tissues, but formic acid, in the proportion: Acid formic, one part; alcohol, two parts. It was a curious fact that the bacilli occurred in patches, while in other parts, apparently equally diseased, they were present in small numbers.

CORRESPONDENCE.

ACUTE TONSILLITIS, AND ITS TREATMENT BY BICARBONATE OF SODA.

To the Editor of THE MEDICAL NEWS.

SIR: In THE MEDICAL NEWS of August 11th I find a very interesting article on the treatment of tonsillitis, the writer recommending the compound guaiac gargle, and constitutional treatment if called for. About a year ago I saw a paper on this very subject in your JOURNAL, advocating the use of the bicarbonate of soda, which I have used ever since with remarkable success, so much so that in only one case, out of fourteen cases of acute tonsillitis which I treated in this manner, did suppuration occur. Of all the cases which I have thus treated, permit me to relate the following typical case, which will serve to show the value of the drug in this affection.

On the 20th of last November, a young man aged twenty-two, German, while working as a farm hand in a malarial region, came to me with the following history. Two days ago (on the 18th), he had had a slight chill, which was followed by a light fever; with this he experienced some pain upon swallowing. The constitutional and local disturbances grew constantly worse, till he decided to see me. Upon examination I found the tonsils and fauces so inflamed, and tonsils so enlarged, that deglutition was not only exceedingly painful, but almost impossible, as a large portion of the liquid food (the only kind of which he could partake) would, in the act of swallowing, regurgitate through the nostrils. He could not open his mouth over half an inch. Respiration was painful and more frequent than normal. Temperature 102°, pulse 108. Phonation was painful, and voice so changed as to render it difficult to understand him. Saliva accumulated constantly in large quantities in his mouth. I blew, by means of a glass tube, bicarbonate of soda on the inflamed tonsils and fauces, and ordered cold towels to be applied to the neck. Besides this, he took five grains of quinine every four hours. Next morning there was little or no fever, and the inflammation of tonsils was subsiding. I applied four times in three days the bicarbonate of soda in the manner described (which may, however, also be applied with a camel's-hair pencil), and the inflammation had entirely subsided on the fourth day. No suppuration occurred.

In my opinion, bicarbonate of soda is a valuable remedy in acute tonsillitis, but it should be applied thoroughly, and at least once or twice in twenty-four hours. If resorted to in time, it will almost invariably prevent suppuration.

Respectfully,
A. H. VINKE, M.D.

ST. CHARLES, MO., August 16, 1883.

MEDICINE IN CHINA.

To the Editor of THE MEDICAL NEWS.

SIR: It is desired to call attention to some medical facts which came to my knowledge during a recent visit to China.

I do not propose to treat of Chinese medicine, *per se*, but simply to state a few truths of the general practice of our art by our colleagues, American and English, now residents in that country.

I will confine my remarks more especially to the city of Tien Tsin, in Pi-chi-li, northern China.

As regards the practice of medicine among the Chinese themselves, there is none, according to our ideas.

It is true, they have many medicine-men throughout their vast possessions; but these must be classed under the head of charmers, charlatans, and quacks, *et al.* There is an absolute ignorance of all that pertains to anatomy, physiology, and chemistry, and such knowledge as necessarily belongs to the healing art. Thus, I repeat, there are no medical practitioners among the Chinese, as a people, worthy the name. They have no materia medica to which one can refer for a history, classification, and properties of their drugs; no pharmacopœia, so far as I am aware.

The vaunted qualities and excellences of many of their nostrums are set forth in local pamphlets, similar in kind to the advertisements of irregular doctors in other countries. But no official or national preparations of vegetable or mineral substances exist. In their drug shops they have a large number of dried plants, from which they prepare extemporaneously various teas, effusions, and lotions; also, powders and plasters. They do not appear to use tinctures of any kind; in fact, so far as the preparations in the stores go, no fluids are to be seen.

Of course, opium, camphor, rhubarb, gamboge, gentian, and catechu are found, and it seems that some of the virtues of each are understood and appreciated. From all indications, however, their whole plan of treating disease is empirical, and borders very much on the miraculous and the witchcraft order. Of surgery, their knowledge and practice are most primitive, as can readily be surmised after the statement, that they know nothing whatever about anatomy. This must continue to be the fact so long as the Chinese hold religious beliefs as now, for this all-important branch of medicine cannot be studied practically, as no dissections are allowed by their laws. It is hoped that some of the Chinese students in the United States will take up this study at the colleges where they are being educated, and that upon their return to China they may put the knowledge thus acquired into practice in a surgical sense. But, until the Chinese idea as to the great hereafter is materially changed, there will be no advance in the study of practical anatomy.

The existing fear and veneration of their dead make any attempt at examination of a cadaver quite out of the question at present.

It is this religious dread of disturbing the spirits which they declare remain near the bodies of their dead ancestors, that constitutes one of the great objections to the building of railroads in the Flowery Kingdom.

No Chinaman will permit, if he can prevent it, any tampering with the body of a relation or friend; or even with the grave of such, as would necessarily be the case in the construction of a highway, as he believes the eternal happiness of the defunct, as well as his own earthly existence, depends, in great measure, upon certain religious functions which he and his family observe, from time to time, near the sepulchre or body of the deceased.

In all the foreign settlements in China, as might naturally be expected, are resident physicians from the various quarters of the world; and in the more prominent towns are to be found men of fine abilities and considerable experience. To these the educated and well-to do Chinese in the immediate neighborhood frequently apply when urgently in need of medical assistance; but, in proportion to the immense masses of the people, these few are numerically as drops to the ocean. Owing to the physical hardships which almost every Chinaman experiences in early life, those who live to the age of puberty are like the Indians of this continent—about impregnable to ordinary ailments. In other words, only those endowed with strong constitutions and great vital powers are likely to survive childhood and youth. The feeble of body are exceedingly likely to perish in the early struggles for survivorship.

It is amusing, and not a little interesting to a foreigner, to witness a Chinese doctor examining a patient. The scientific gentleman takes very few minutes to make a diagnosis; for it is of some moment to him, that he recognize, so to speak, at a glance, where the disease exists with his patient; otherwise, his reputation might suffer.

The doctor looks at the invalid through his glasses—no Chinaman can be adjudged intelligent or learned, by his countrymen, unless he wears spectacles, and the larger they are the more important and respectable the practitioner is presumed to be—and at once demands where the trouble is, and immediately after the sufferer has indicated the seat of difficulty, the learned gentleman exclaims, "Oh, yes! I knew it was just there;" and he then examines both radial pulses, first the right and then the left, and confirms the diagnosis by stating that the pulse of the side affected beats so differently from that on the sound side. This settles the matter, in the opinion of patient and physician, and without further ado the treatment is advised and put into practice.

In the great majority of cases the foregoing is the entire routine of examination. Any additional rational or physical exploration is rarely observed. The Chinese practitioner resorts to measures to make known his fame and medicines, which bring vividly to mind the modes of procedure taken by certain itinerant doctors in this land of freedom. He selects a prominent part of the city or town for his office; puts out his conspicuous signs and promises in the most public positions; has one or more sedan-chairs—corresponding to our carriages—with gaudily-dressed carriers, and employs men to run about the principal streets to attract as much attention and cause as much commotion as possible. When not engaged in his office, he has his servants carry him at the top of their speed through the crowded thoroughfares, it being an important part of their functions to ask, or demand, that all passers get out of the way for the famous doctor Wing Lung, who cures all manner of diseases, is in great haste to see a dying man whose life he has promised to save. And it is a portion of their usual programme to have a body of retainers rush about the town, demanding if any one has seen the mighty doctor Wing Lung, as he is wanted at once—"here, there, everywhere?" One point in their practice is worthy of consideration; when they are actually called to see, or prescribe for a patient, and not on dress-parade business, it is an invariable rule to obtain the usual fee before acting. Pay in advance for all advice is a cardinal point which is not overlooked, no matter what the circumstances.

Counter-irritation is very popular with the profession and the laity; the actual cautery, rudely applied, is frequently put into service. Setons, blisters, and caustics are also favorite modes of "making impressions." Tiger-claws and teeth in powders, dried toads, lizards, snakes, and bugs are prominent in the armamentarium of the celestial physician. Urine from a youth is judged to be a tonic; and the excrement of various animals finds notable places in the materia medica of this people. It is to be remembered, that the Chinese woman lives an almost excluded existence. Upon no account can a man, not a relative, be permitted to see, much less to touch her, no matter how ill she may be. Domestic practice has to do for her case, and if there are exceptions to this law, they are so few as to be isolated and unknown in the great mass of cases. If there were no other reasons for the Chinaman's constant thanks to the power that made him a man, this well-known unrelaxing custom would seem to be sufficient cause for his gratitude. This brings me to speak of a lady physician, now resident in Tien Tsin, in the vice-royalty of Pi-chi-li; and certain circumstances connected with her labors among our celestial friends. It scarcely need be mentioned in this paper, that there are no Chinese female practitioners of medicine; not even "irregulars" of their own stamp. For reasons already given, the gentle sex has an exceedingly tough time of it when ill; indeed, this statement may describe her life in its entirety. Even in child-bed, the unfortunate woman, be she rich or poor, has no assistance as we are accustomed to afford a patient in that state. It is the fact, that she is surrounded by the women of the family, who, as a rule, let nature take her course; but should there be difficulties, such as an arm presentation for instance, summary measures are instituted; and if either mother or child escapes with life, the fact may be regarded—as indeed it is—marvellous and noteworthy. That such should be the case is not difficult to understand, when we are told that the usual mode of procedure in such an event is to push the protruding arm back into the uterus if possible; otherwise, it is cut off; and to aid in the delivery, the expectant mother is sat upon by one or more individuals, or she is pulled about the floor, or both successively. We have no knowledge as to how they manage post-partum, or, in fact, any hemorrhage. Statistics of any kind are not recorded for the benefit of foreigners, as regards the practice of medicine; save the reports given by the custom house physicians, and those voluntarily made by the missionary and other regular practitioners, we have no data concerning vital statistics in China. Whatever knowledge and experience a Chinese doctor may acquire, he keeps it to himself, so far as the outside world knows. As concerns the diseases and most else of Chinese women, we are utterly in the dark.

To return to our lady physician, Dr. Howard. This lady was educated at Ann Arbor, Michigan, and, eventually graduating in medicine, was sent to the East Indies as a medical missionary by one of the American societies. Her first field of duty was at Pekin, the great capital of the Tartar rulers of China. As it is a well-known fact, with all mission-work in that conservative land, Dr. Howard's labors were making very slow progress when an event occurred which has actually made a revolution in the field of medical possibilities in the last. It will be well to give, somewhat in detail, an account of the circumstances which have resulted in so much good to the people interested. We all know that Li Hung Chang is the viceroy of Pi-Chi-li, one of the great political divisions of the Chinese Empire, and is the absolute master of over 20,000,000 of beings.

He resides in the imperial city of Tien Tsin, the port of Pekin, situated on the Psiho river, some sixty miles from the sea, and about eighty distant from the capital. Now, Li Hung Chang, in addition to being governor of the said province, is one of the senior generals of the empire; in point of fact, he is the most distinguished military mandarin in the country, and commands by far the most formidable body of troops in the army. Moreover, Li is in reality the head of foreign affairs of China, and wields a mighty influence in the government, both as regards her domestic and outside policy.

This viceroy is a progressive man, and encourages the advancement of foreign ideas and measures among his countrymen, as far as is consistent with their great conservativeness. He is necessarily obliged to go very slowly in a land where 350,000,000 of people look with a jealous eye on any change in a programme which has predominated with them all from time immemorial. Well, the principal wife of Li Hung Chang was ill, and her family became much alarmed about her. At this time—1880—it so happened that the viceroy had a friend in high esteem, Mr. Pettie, a former vice-consul of the United States at the port of Tien Tsin, for whom he sent to ask advice in the hour of distress. This gentleman appeared promptly, and had the circumstances explained to him: he lost no time in urging the governor to call in a foreign doctor. A more radical idea could scarcely have been proposed to any Chinaman; and it is quite within the bounds of possibility to say that, had any of the king's subjects made such a proposition, he would have been decapitated at once for his temerity. The American argued that if the facts were as stated by the attendants of Lady Li, she would soon perish unless intelligent and professional assistance came to her relief at an early moment.

The viceroy is a markedly learned man, and it required no great amount of explanation to make clear to his mind that prompt action was demanded in the premises, and he sent for Dr. Mackenzie, an English physician, attached to the London Mission, living in the foreign settlement near Tien Tsin. The doctor lost no time in obeying the imperial mandate, and, once in the Yamen, Mr. Pettie soon put him in possession of the main facts of the case.

As Dr. Mackenzie speaks the Chinese language markedly well for a European, he was not long in making out what the trouble was—viz., prolapsus of the uterus. It must here be noted that the physician was not permitted to see the illustrious sufferer. Such an idea—a man, a stranger, and a foreigner to go into a lady's room—was not to be considered for an instant, not even by so radical a Chinaman as Li Hung Chang. Thus the doctor remained in an out-room, and explained, as best he could, to the invalid's women-folks, the means to be taken to replace the organ in its proper position. But partly through fright, partly through want of knowledge and skill, and the usual difficulties attending such an operation, it was found impracticable to restore the parts to their normal condition, a fact not very marvellous, all the facts considered, to any one familiar with the subject.

In this dilemma, Dr. Mackenzie bethought him of Dr. Howard, the lady whom we mentioned a moment since, who was not only a friend of the doctor, but a colleague, then living in Pekin. He explained the situation to the viceroy, and asked if there would be any objections to this lady's assistance being invited. Li Hung Chung consulted with his advisers and Lady Li, and it was shortly determined that the lady physician should be summoned.

Dr. Howard came down those eighty miles in a springless, two-wheeled cart over one of the roughest roads on this or any other world; and getting at once a synopsis of the case from Dr. Mackenzie, she went to the patient, and quickly succeeded in returning the displaced organ, thus making the lady comfortable, and putting her friends mentally at ease. Lady Li was not long in recognizing the service done her by Drs. Mackenzie and Howard, and a warm friendship sprang up between the latter and her royal patient from their daily intimacy, for Dr. Howard remained in Tien Tsin to take care of Lady Li. Handsome and valuable presents were the least of the benefits coming from this incident. Li Hung Chang also appreciated the labors of the Caucasian physicians, and, what is more, the intelligence and system of which they were the exponents. He became interested in foreign medicine, and being, as already stated, a go-ahead man in every sense, began to encourage the work of Dr. Mackenzie, who was laboring assiduously among the invalid poor of the city, in connection with his mission. Dr. Mackenzie became the medical adviser of the viceroy, whose influence quickly had its effect upon the members of the court and other prominent people. This good physician was allowed to hold a clinic at one of the large temples in Tien Tsin, to which flocked, by hundreds, the lame, the halt, and the blind males of the neighborhood. It is to be stated that the doctor had a small dispensary on the outskirts of the foreign settlement, where he treated, gratuitously, such invalids as came for assistance, the London Mission supplying medicines, appliances, and instruments to a certain extent. In this contracted place, he saw and prescribed for hundreds of sufferers during each month; did such surgery as was consistent with out-door practice, and even, at times, performed major operations in extreme cases, feeding and providing for the invalids at his own expense. Having installed himself in the temple, as mentioned, and being thus under the immediate protection of the viceroy, patients came in crowds to receive aid and advice. Li Hung Chang did not do things by halves; he granted a sum of money with which to purchase medicines, and agreed to pay for any and all instruments that the doctor might need in this practice. And this was not all; for seeing and recognizing the wonderful interest that the viceroy evinced in foreign medicines, his followers and subordinates set about raising money to build a hospital for Dr. Mackenzie. A sum sufficiently large was soon accumulated to pay for such an institution as proposed, and in a short time it was commenced. This hospital was built by Chinese carpenters, and, to allay as many prejudices as possible, the native ideas of architecture were followed, save in minor particulars. It was finished in November, 1880, and, on December 2d, formally opened by the viceroy in person, assisted by various Chinese officials of high rank, in the presence of all the foreign consuls, distinguished citizens, and representatives of the several ships of war then in port. His excellency Chung Tso Ju, the present Envoy Extraordinary and Minister Plenipotentiary from the Court of Pekin to the United States, Spain, and Peru, who was at the date mentioned latai of Tien Tsin, and one of the prominent lieutenants of Li Hung Chang, took an active part in supporting this foreign institution by his great influence and wealth. The hospital contains about forty beds, having the necessary dispensary, waiting, operating, and lecture-rooms.

Without going into the details of its peculiar arrangements, it may be admissible to state that the character of these beds is one of the most curious of its features. They are constructed of large bricks set in mortar, having a fireplace beneath each, in which straw, hay, and brush, are burned for heating the whole. Thus, each patient has his own fire by which all his food is cooked in utensils furnished by himself. Now, when a Chinaman takes to one of these beds, which might, with propriety, be termed a brick-oven, he immediately proceeds to divest himself of all clothing down to the skin; nothing remaining on the body save, it may be, a piece of cloth about the loins. He then places himself between two thick, coarse, plank-like quilts, with his neck upon a wooden pillow. This is the Chinese fashion of preparing for and going to bed, and although it has drawbacks, yet it allows, certainly, of free inspection of the individual at a moment's notice. And let it be remembered, that for nearly half the year the climate of Tien Tsin is arctic in severity, there being no artificial heat in the building save that derived from the burning brush or straw in the small fireplaces beneath the so-called beds, which does little to raise the general temperature of the wards. It is not uncommon for operations of magnitude to be performed in an almost freezing temperature, the patient being nearly nude, which fact illustrates, in a measure, the great vital powers of this hardy people.

At the dispensary in the temple, some two hundred or two hundred and fifty out-patients were seen and attended four times weekly, a record being kept of each by Dr. Mackenzie, assisted by several Chinese students, who were at that time studying the rudiments of physic under the doctor's tuition. It is frequently the case, that one or more of the medical officers of foreign war-vessels in port avail themselves of the gentleman's courteous invitation, and assist him in these trying and extensive labors. There is rarely any difficulty or delay in obtaining aid when operations are to be performed. Minor surgery is done on the moment at the temple; but such cases as require hospital treatment are sent to that institution, provided the candidate for operation can bring his bedding, fuel, and is able to buy his food.

Unfortunately, there are as yet no funds for these purposes. However, it is thought these necessaries will be supplied in the near future. Diseases of the eye and ophthalmic surgery are, by all odds, the most frequent. Dysentery, hemorrhoids, ring-worm, and syphilitic affections are very common. Few acute cases are seen, as invalids, so far as regards the immense majority, only seek foreign assistance when they have failed to find relief through their native doctors. But once they place themselves in the hands of the surgeon, any doubts or hesitation they may have had quickly vanish, and their trust in the skill and ability of the operator is implicit—they coöperating with him fully and to their uttermost. Anæsthetics are not administered, save in major operations.

The Chinese bear surgical interference markedly well. Owing to the total disregard of all hygienic and sanitary precautions and rules, it is rather marvellous that so many receive benefit from treatment; for it is difficult to imagine any people who have fewer comforts of life than do the great masses of the Chinese. Indeed, agreeably to our ideas of the necessaries of life, they have none whatever.

To return to Dr. Howard. Through the influence of Lady Li, the doctor has a part of the temple already alluded to set apart for her clinics, where aid and advice are given to the indigent women sufferers. Of course, no man is permitted to take part in these labors; although Dr. Mackenzie is occasionally called by Dr. Howard to consult as to certain special cases. A gentleman of New York has sent a considerable sum of money to Dr. Howard, to aid in building a hospital for native women; and Lady Li is coöperating in this good work. But the women of the Celestial Empire are kept so much excluded from public view and association, that time must elapse before any great advance is made in permitting the public gathering, even for health considerations, of the female element, save among the most abject and poverty-stricken of the people, who have no position or reputation to guard or lose. It remains to be said that, so far as I am aware, the Chinese have no eleemosynary institutions of any description. The indigent sick receive no care or aid, save it may be from passers. As long as able they wander about, or lie in public places in hope of obtaining, now and again, some assistance from the charitably disposed. The insane are either cared for by their families or run in the streets; those too violent to be left thus at liberty, are put in chains and treated as, and with, malefactors. There are to be seen in the great city of Tien Tsin, hosts of the sick, the poor, the demented and crippled, each winter with Fahrenheit's glass standing below zero, without clothing, save, at times, a fragment of an old carpet, bag, or like covering. Shelter they have none, if we except an upturned cart, or the lee of some building or fence; and apparently they have been long without food—thus being at once among the most abject and miserable of beings. In all the important foreign settlements are to be found, however, dispensaries, and in some hospitals, into which are received many of these unfortunate people; and the various missions aid and supply the wants of the sick where it is practicable to do so. Fatty Crystals.—In a former number allusion was made to the medical expert testimony in the lard investigation before the Chicago Board of Trade. Under the microscopical evidence for the defence, it was stated that Dr. W. T. Belfield was the discoverer of the crystals characteristic of lard and tallow. Facts, entirely new to us, having very recently come to light, the following statement with reference to the first recognition of these crystals is rendered necessary in justice to the real discoverers and to Dr. W. T. Belfield:

In July, 1881, Dr. B. P. Rose was retained by Messrs. Fowler Bros., to investigate the subject of lard and its adulterations from a chemical standpoint. In January, 1882, Dr. I. N. Danforth was requested by Prof. N. Gray Bartlett, of the College of Pharmacy, to make a microscopical examination of the same subject. The attention of both gentlemen was directed to finding crystals characteristic of pure hog fat and its adulterations. Dr. Rose removed the olein from the specimens examined, by means of absolute alcohol or ether, dissolved the residuum in turpentine or other members of the balsamic series, and, from the slow evaporation of such menstrua, recovered the rhomboidal plates with bevelled edges, the crystals now regarded as characteristic of hog stearin.

Dr. Danforth, after the removal of the olein, employed ether as a solvent of the residual stearin, obtained the lard crystals previously recognized by Dr. Rose, and, in addition, made the important discovery of the acicular, rosette crystals now believed to be characteristic of beef stearin.

The observations and experiments of Drs. Rose and Danforth were confirmed by Dr. P. S. Hayes and Dr. S. J. Holmes in January, 1882.

It is plain from this survey of the facts in the case that the credit of the discovery of the rhomboidal plates, with bevelled edges, characteristic of hog stearin, belongs to Dr. Rose; while Dr. Danforth must be credited with the first recognition of the acicular, rosette crystals characteristic of beef stearin.

Dr. W. T. Belfield applied the processes of Drs. Rose and Danforth and took the excellent micro-photographs of the crystals, which were presented for inspection to the members of the Board of Trade. The statements, published by various misinformed individuals, that cuts of lard and tallow crystals, as such, occur in the works of Husson and Gamgee, are entirely erroneous.

LIGATION OF THE OVARIES.—Dr. E. C. Dudley, Professor of Gynecology in the Chicago Medical College, has been engaged, for some time past, in experimental inquiry as to the effect of ligation of both ovaries in the lower animals. Up to the present time he has experimented solely upon dogs. The abdominal cavity is opened by an incision in the median line and both ovaries are secured by ligatures passed around their peritoneal attachments, without inclusion of the Fallopian tubes. No untoward symptoms have been observed after the operation. As was to have been expected in dogs, no peritonitis has ever resulted, and the abdominal incision has always healed by first intention. At the termination of various intervals the dogs are killed, and the ovaries examined. In every case the ovaries have been found to be greatly atrophied. After ligation, the ovary is in very much the condition of the pedicle of an ovarian tumor. It does not slough, but a collateral circulation is promptly established, which prevents gangrene. The nervous connections of the organ are completely interrupted. The constitutional effect of this interruption of the channels of nervous communication has not been observed fully as yet, but will constitute a future study. It is possible that a "collateral" nervous connection may be ultimately established. The effect upon menstruation has not been determined, but will receive due attention in the progress of the research. The objective point of these experiments is very evidently an important modification of Battey's operation.

FREUND'S OPERATION.—Dr. Roswell Park performed Freund's operation of total extirpation of the uterus upon a woman, suffering from scirrhous carcinoma of the collum uteri, ten days ago. A small parovarian cyst was found upon the right side, and was also removed. The woman died seventy-two hours after the operation, probably of pyæmia. Bichloride of methylene was employed as the anæsthetic. The autopsy revealed a slight peritonitis, but no hemorrhage.

BERLIN.

(From our Special Correspondent.)

THE TUBERCULOSIS QUESTION AND THE ARMY.—Last year the medical department of the Ministry for War issued a circular urging upon the medical officers with the army to give the utmost attention to beginning tuberculosis among recruits, and, as far as possible, not to enroll suspected individuals at all, or, if enrolled, to dismiss them from the service in the earliest stages of the disease. Hospital patients suffering from unquestionable tuberculous affections are to be isolated, and their sputa are to be disinfected.

It is firmly hoped that the death-rate from tuberculosis, already diminished to 3.8 per thousand (see official report for 1879–80) by the sanitary improvement of barracks and hospitals, may thus be reduced to its lowest possible degree. In relation to this question, the microscopic examination of the sputa lately has become of the greatest importance; therefore, first-rate microscopes recently were distributed among all the larger garrison hospitals, in order to facilitate an early diagnosis.

Prof. Fræntzel (who is also an active army surgeon), in a paper read before the Berlin Military Medical Society, highly congratulated the medical authorities of the War Department upon this step, which he thinks will be of great benefit to the army. He said he was proud to claim the priority among German clinical teachers in having unhesitatingly adopted the germ theory of tuberculosis, and scrupulously applied its logical deductions to clinical practice. Continued researches, now comprising upwards of five hundred cases, served to confirm his former views and statements about the diagnostic and prognostic value of the tubercle-bacilli found in the sputum (see *Berliner klin. Wochenschrift*, 1882, No. 45, and *Deutsche med. Wochenschrift*, 1883, No. 17).

As for treatment, a series of careful experiments, made under the regular control of Koch and Goffky, have taught him the inefficacy of all inhalation methods. It seems as if the medicaments employed in this way do not reach the diseased parts of the lungs, since even those which proved to be the strongest poisons against pure cultures did not in the least diminish the number of the tubercle-bacilli in the sputum. On the other hand, he rejects as useless and rather cruel the direct application of strong antibacteric solutions (bichloride of mercury!) to the lung-tissue, as recently performed by means of a Pravatz syringe in some clinical wards. So we find ourselves restricted to internal medication, and must try to overcome the enemy in that way. Till now, Fræntzel ascribes the best results to the creasote treatment, after the formula of Bouthard and Gimbert, which he adopted a couple of years before the germ theory (see *Charité-Annalen*, iv., 1879, p. 278).

LESSER'S ATLAS OF FORENSIC MEDICINE.—Forensic medicine in some way may be called the mother of pathological anatomy; but there is no doubt that during the rapid progress of the latter in the middle of this century the mother proved somewhat jealous of her own child. To-day this jealousy has subsided, and forensic anatomy, much to its own great benefit, has undergone a process of regeneration on the broad basis of pathological knowledge. This knowledge, of course, should be gained by earnest practical work in the dissection-room; nevertheless, the State physician, even if he be the best pathologist, will often find himself at a loss in face of those rare occurrences which are peculiar to forensic practice. This gap can solely be filled up by pictorial works representing the characteristic changes caused by those properly forensic emergencies, as poisoning, hanging, drowning, etc.

A modern standard work of this kind till now was wanting, at least, in Germany, the older ones, especially that of Casper, exhibiting only a few specimens from an obsolete point of view, and with very poor technical means. In a lucky appreciation of this want, six years ago, Dr. Adolf Lesser, then a young assistant to the Institute of State Medicine, in Berlin, after having well trained himself in pathological anatomy under the very eyes of Virchow, undertook to describe and have painted every characteristic specimen which happened to be observed in the ample forensic practice of the metropolis. For this purpose, he allied himself with a well-gifted artist, a pupil of A. v. Werner, whose school mainly excels in coloring. Color, indeed, is of the highest diagnostic value in forensic practice; sometimes color alone will tell us if a change is due to inflammation or to putrefaction; color will teach us, earlier than chemical inquiry, if the blood be changed by some gaseous poison; color will guide us in the differential diagnosis between a chronic and an acute abscess or hemorrhagic focus in the brain.

The fruit of these combined efforts of art and science is now lying before us. Lesser's *Atlas der gericht-*

lichen Medicin (Berlin, A. Hirschwald) may indeed be called a standard work, which fairly rivals the great atlases of Bright and Cruveilhier, and possesses the advantage that the highly finished technique in color-printing has succeeded in multiplying the plates in a quite unprecedented perfection. Perhaps the best recommendation is given by the preface, written by Virchow himself, who "can say, without exaggeration, that better colored plates hardly exist in pathological literature."

The first and second fasciculi, now ready, contain six plates each, with thirty-two figures, representing the macroscopic and partly the microscopic changes caused in the œsophagus and stomach by a long series of different poisons, as carbolic acid, nitric, sulphuric, oxalic acid, hydrate of sodium, bichlorate of mercury, camphor, phosphorus, prussic acid. Plates XI. and XII. exhibit some rare idiopathic changes, which might erroneously be taken for cases of poisoning. The text gives the exact pathological and forensic history of each case. The whole work will contain thirty-five folio plates, and will constitute an extremely valuable addition to our literature.

THE CHOLERA IN EGYPT.—The general cholera mortality rate has diminished during the past week. The disease appears to be dying out at Cairo, but remains about stationary in Alexandria. The mortality for all Egypt has markedly fallen.

The official returns of cholera deaths are as follows:

	Cairo.	Alexandria.	Total for Egypt.
August 14, . .	9	40	376
" 15, . .	5	. .	467
" 16, . .	6	44	433
" 17. . .	. .	41	. . .
" 18, . .	5	50	310
" 19, . .	4	32	182
" 20, . .	3	43	193

On August 14th fifty-five deaths were reported at Damanhoor.

The total number of deaths from cholera among the British troops in Egypt since the outbreak of the disease to date is 140.

On the 16th the Khedive again visited the cholera hospitals at Alexandria and spoke words of encouragement to the patients.

M. PASTEUR'S MISSION.—The French cholera mission, under M. Pasteur, arrived at Alexandria on the 16th.

CHOLERA IN INDIA.—Two hundred and twenty deaths from cholera in Bombay were reported on the 17th as having occurred during the preceding fortnight.

CHOLERA IN SYRIA.—On August 19th another death from cholera was reported at Beyrout.

CHOLERA PRECAUTIONS IN VIENNA.—The Vienna Board of Health has instituted a thorough system for the immediate cleaning and ventilation of overcrowded houses, flushing of the sewers, analysis of drinking water, and purification of the city atmosphere. The City Physician of Vienna has also commenced the personal inspection and ventilation of lodging houses, and given orders for the sorting and disposal of animal refuse, skins, bones, feathers, rags, etc., in the neighborhood of dwelling rooms.

YELLOW FEVER AT PENSACOLA.—Yellow fever has broken out at the U. S. Navy Yard at Pensacola. Surgeon A. M. Owen, U. S. N., in charge of the Medical Department of the Naval Station, Pensacola, under date of August 16th, advised Surgeon-General Wales, U.S.N., as follows:

"I have to report the appearance of yellow fever among the marine guard of this station. I have two well-marked cases now in the Naval Hospital, and other cases of fever of a suspicious character. And I beg to put on record, that I believe there are, from general rumors, sufferers with the said disease among the residents of the reserve."

The Secretary of the Navy also received a telegram from Commander Welch, commanding the Navy Yard, Pensacola, as follows: "Surgeon Owen reports a case of yellow fever in the Marine Guard; man is in hospital this evening; moved the quarter to second story of building. Relieved guard, numbering thirty-eight men, from all duty in order to isolate them from other persons. Surgeon Owen recommends transfer of guard North as soon as possible. The case was decided last evening. Two other men sent to hospital to-day. Cases not decided."

Instructions were telegraphed to Commander Welch to transfer the Marine Guard to Cape Anson, six miles from the Navy Yard, and to make all the sanitary arrangements necessary for the health of the yard. Orders were also issued to Surgeon Martin, at New Orleans, to proceed to Pensacola and render all assistance in his power.

On August 17th, Surgeon Martin arrived and took general charge of the hospital, and Dr. Harges at the yard. The Department was informed of Surgeon Owen's illness with the fever, and of the death of the first case reported, and that the Naval Station had been quarantined by Pensacola since noon of the 16th.

It appears that on the 16th Surgeon-General Hamilton received a telegram from the President of the Board of Health of Pensacola, requesting aid to establish a cordon around the Navy Yard. The Collector of Customs at Pensacola, was immediately directed by the Acting Secretary of the Treasury to employ ten patrolmen to aid the Board of Health in maintaining quarantine. The Collector on the night of the 17th, reported that forty men would be required for the service, as the patrol line was five miles in length. Surgeon-General Hamilton, with the approval of Acting Secretary French, on the following day telegraphed to the Collector of the Port, that on the filing of an affidavit by the Mayor of the city and the President of the Board of Health, that they are unable to employ a sufficient quarantine force, to employ as many patrolmen as necessary. The affidavits were duly filed, and the patrol was placed on duty on the evening of the 18th.

On August 19th, the Department was notified of the existence at the Navy Yard of six cases, including Dr. Owen's child, and of one death from the disease on the 17th.

On the 20th, Surgeon-General Hamilton of the Marine-Hospital Service was informed by telegraph by Surgeon White, at Pensacola, that no new cases had developed at the Navy Yard during the preceding forty-eight hours; that up to date there had been eight cases and three deaths, and that the fever was confined to the yard and hospital.

Surgeon Owen is reported to be in a critical condition.

YELLOW FEVER IN HAVANA.—There were forty deaths at Havana from yellow fever, for the week ending August 18th.

INVESTIGATION OF YELLOW FEVER.—The Brazilian government has appointed DR. DOMINGO FREIRE to investigate the causes of yellow fever, and study the following points. 1. Microscopic observations, and cultivation of the microbes already found. 2. Attenuation of the virulence of these microbes, and experimental inoculation of animals, with a view to, if practicable, human inoculation. 3. Action of salicylate of soda in the treatment, both hypodermatically and by mouth. 4. Autopsies for the purpose of determining the true pathological lesions of the disease. All the necessary instruments and apparatus will be furnished him, with three assistants.

Smallpox in New Orleans.—There were sixteen deaths in New Orleans from smallpox for the week ending August 11.

Pleuro-pneumonia in Connecticut.—The following is a copy of the report received at the Treasury Department concerning the outbreak of pleuro-pneumonia in Connecticut:

United States Treasury Cattle Commission,
West Newton, Mass., August 16, 1883.

Hon. H. F. French,
Assistant Secretary of Treasury, Washington, D. C.

Sir: I have to report an outbreak of lung plague in the town of Salem, State of Connecticut. On the 16th of April last a cow was purchased by H. E. Williams, of Salem, in Jersey City, near Hoboken ferry, of a man named Durham. Early in July a disease appeared among the cattle owned by Mr. Williams, three of which died or were killed by the owner. The lungs were examined by Prof. Leantarel, American Veterinary College, and by Dr. Rice, V.S., of Hartford, Conn., who pronounced the disease to be lung plague. By request of the State Cattle Commissioners, I visited the farm of Mr. Williams on Tuesday, the 14th inst. Of the remaining animals of the herd, three are affected with lung disease in the chronic form, the form has not fully passed through the acute stage of the disease. An adjacent farm is owned by Captain Leaman, who has a large herd of cattle, one of which has died. Both herds are in quarantine, by order of the State Commissioners, who appreciate the importance of preventing the spread of the disease, and, having full authority, will doubtless prevent its further extension.

Very respectfully,

E. F. Thayer.

The Treasury Department feels no apprehension as to the spread of the disease beyond its present locality. Whether the cow brought from Jersey City came from a herd recently imported is not known at the Treasury Department. Salem county is in the southern part of the State, about twenty miles from Long Island Sound.

The Need of the Library of the Surgeon-General's Office.—At the meeting of the American Library Association held at Buffalo, N. Y., August 14th to 17th, the condition and needs of the Washington libraries were considered, and resolutions were unanimously adopted to the effect that it is the opinion of the Association that a suitable building for the accommodation of the National Library, and also a separate fireproof building for the Medical Library and Museum of the Surgeon-General's Office should be built as soon as possible, and that the Executive Committee shall prepare a memorial to Congress, setting forth the necessity for these buildings, and offering in behalf of the Association any information on the subject which may be desired, and which they are able to furnish.

Index Catalogue of the Library of the Surgeon-General's Office.—We learn that the fourth volume of the *Index Catalogue* is now in the hands of the binder, and will be ready for distribution by the end of the month. It carries the work to *Fiz*. The appropriation for this work will be exhausted with the fifth volume, and, unless Congress makes an appropriation for completing it, the publication will cease.

Tri-State Medical Association.—The ninth annual meeting of the Tri-State Medical Association, will be held in Indianapolis, on September 18th, 19th, and 20th, 1883.

Virginia State Medical Society.—The fourteenth annual meeting of the Virginia State Medical Society, will be held at the Rockbridge Alum Springs, on September 4th, 5th, and 6th, 1883. The Address will be delivered by J. Edgar Chancellor, M.D., of Charlottesville, Va. The President, Wm. D. Cooper, M.D., of Morrisville, will deliver his Address on Wednesday, September 6th. A number of interesting papers will be read. A large attendance is expected, owing in great part to the liberality of the proprietor of the Rockbridge Alum Springs, who makes no charges to Fellows and Delegates.

Dr. Flint at the Dinner of the British Medical Association.—Dr. Austin Flint, in proposing the toast of the "British Medical Association," said he desired to express his thanks for the honor of the invitation to attend the fifty-first meeting of the Association, and to participate in some small degree in the sectional work. He could not adequately express the satisfaction he had derived from his attendance. Having reached a period of life when happiness was derived from retrospection rather than from anticipation, so far as the present life was concerned, he desired to say that the social and professional events of that meeting would ever hold a prominent place in his memory. His official connection with the American Medical Association rendered it proper for him to state that, for the most part, American institutions—political, literary, educational, and philanthropic—were based on their knowledge of the institutions of Great Britain, which the Americans rejoiced in calling their "mother country." The American Medical Association was modelled closely upon the British Medical Association; and, in view of a relation which he might venture to call maternal, he was sure they would be gratified to know that the transatlantic daughter was zealously and dutifully striving to follow, at a respectful distance, in the footsteps of an honored mother. As an evidence of the alacrity with which the institutions of the old were introduced in the new world, he might mention that the British Medical Association in age exceeded that of the American Medical Association by only fifteen years. It had always appeared to him that it must be a pleasing reflection to Englishmen that the English language was, as no doubt it would be for all time, the language of the vast continent of North America. English literature was American, and the proceedings of the British Medical Association commanded hardly less interest in the new than in the old world. He would even venture to state that there was not a hamlet, within the limits of the United States, so distant or so obscure, that the report of the proceedings of the British Medical Association would not be speedily conveyed to it by the *British Medical Journal* and the medical press generally.

Mr. Ernest Hart, in proposing the "Guests," said that they cordially welcomed among them the physicians of America, France, Germany, and their guests from Holland and other countries. Americans they regarded not only as brothers in the profession, but as kinsmen in blood who shared with them the common heritage of history, literature, and science. They were honored by the presence of the President of the American Medical Association, who was so much one of them that they had not put down his name to answer for the toast, but they had assigned that duty to Prof. Tilanus, of Amsterdam, who bore a name which was honored throughout his country, and had been honored for generations.

How they deal with Quacks in Illinois.—A travelling "Indian Medicine Man," Lightfall, by name, but known as "Kansas Jim," recently started business in Decatur, Illinois, and by the aid of a concert troupe, an Indian outfit and other claptrap devices, he, for a short time, did a thriving business pulling teeth and selling "cure-all remedies," the secret of whose preparation he claimed to have obtained from the Indians. Among his attendants was a certain Dr. W. O. Davis, of Peoria, to whom the State Board of Health granted a certificate last April, on the strength of a medical diploma, and under cover of which certificate Lightfall was trying to shield himself from the law.

After fleecing the credulous for a time unmolested, the citizens of Decatur concluded to put a stop to his swindling, and accordingly complained to the State Board concerning Davis, and at the same time caused the arrest of "Kansas Jim" for violating the Medical Practice Act. The State Board promptly revoked Davis' certificate, but "Kansas Jim" had his case taken before a Justice of the Peace and so escaped for the time being. Emboldened by this, he announced his intention of transferring his circus to Springfield, and opening "right under the nose of the State Board of Health." By advice of the Secretary, complaint and information were filed before the County Judge of Macon County, by whom Lightfall was committed for trial under bond of $500. Immediately after filing his bond he proceeded again with his show, but learning that another complaint had been entered against him, involving the deposit of another $500, and that it was the intention to file a new complaint for every repetition of his swindling practice, the "Indian Medicine Man" washed off his war paint, packed up his outfit, and set out for communities where they are more tolerant of charlatans and mountebanks than they are in the State of Illinois.

New Medical Journal.—The publication of a new weekly medical journal, *la Colonie Française* has been recently begun in Valparaiso, Chili. It is published in the French language, and is the organ of the French interests of the Pacific coast.

Death from Chloroform.—A case of death occurred at the Public Hospital at St. John, N. B., on August 1st. The chloroform was administered previous to extirpating the eyeball. About half an ounce of chloroform was administered. In about fifteen minutes after the first inhalation respiration became embarrassed, and then the pulse became affected, the patient became livid, and in five minutes respiration had ceased. Subcutaneous injections of brandy, ether, and a solution of strychnia, and electricity were administered, and artificial respiration practised without avail. The post-mortem examination showed a healthy condition of the organs.

A Second Supra-vaginal Amputation of the Uterus.—Dr. Margary, surgeon to the *Ospitale Maggiore*, of Turin, performed a second supra-vaginal amputation of the uterus, by the vagina, on June 4th. Four days afterward the state of the patient was satisfactory.

Porro Operations.—On June 28th Prof. Porro performed a utero-ovarian Cæsarean amputation, in the Maternity at Milan, on a rachitic woman with pelvic stenosis of the third grade, and a living child was extracted. The result as to the patient is not stated.

The patient upon whom he performed this operation on May 17th has left the hospital, having recovered.

Microscope for Clinical Thermometers.—M. Léon Bloch has recently perfected a small microscope, to be attached to clinical thermometers, by which the scale can be easily read. The microscope is very small and easily attached by means of two small bands which slide up and down the glass.

Honors to Dr. Koch.—His Majesty, the King of Prussia, has graciously granted permission to Dr. Koch to wear the Commander's Cross of the Royal Spanish Catholic Order of Isabella.

Honors to Professor Semmola.—We learn that Prof. Semmola is to be decorated with the cross of the Legion of Honor. The Academie de Médicine has requested this of the Government, and it seems that the request will be cheerfully granted.

Prof. von Budge.—A congratulatory address has been decreed to Prof. von Budge, of Greifswald, on the occasion of his fiftieth year jubilee.

Honors to Prof. von Arlt.—On July 6th, the professors of the Vienna Medical Faculty and about two hundred of Prof. von Arlt's students tendered him an ovation. Short addresses were made by Dr. Friedinger and Student of Medicine Zinsmeister, to which the Professor replied in a happy and graceful manner. Congratulatory telegrams were sent by many of his former pupils who were unable to attend.

M. Pasteur and His Work.—M. Pasteur is one of the few savants who have received substantial honors during their lives. On the day of the National Fête his native town of Dôle was the scene of a solemn public ceremony—the placing of a commemorative tablet on the house in which he was born. The illustrious savant was present, but his emotion so completely overpowered him that he was unable to return thanks, and his speech had to be read by his son-in-law.

The Chamber has just more than doubled his pension of 12,000 francs—making it now about £1,000 a year, with continuation to his widow and children. Lords Wolseley and Alcester may almost feel a pang of envy, but they may derive a sad consolation from the reflection that a want of grace in public acts of this sort is not confined exclusively to English assemblies. There were dissentients in the Chamber the other day—one of them a doctor, who had suggested vaccination for measles at least twenty years ago, and who seemed to think it hard that another should be rewarded for the discovery of a remedy of the same nature for a totally different disease. It was shown, however, that M. Pasteur had given his discoveries to the State, and that if he had chosen to profit by them he might easily have made a large fortune.

M. Paul Bert, his ancient rival in scientific discussion, gives a highly laudatory sketch of M. Pasteur's career of public usefulness. He began by experiments on the nature of fermentation, and his discoveries in this direction have had important practical results in the manufacture of beer and of wine. "Pasteurization" is now practised in the German breweries on a large scale. The results obtained attracted the attention of the Government, and M. Pasteur was requested to inquire into the silkworm disease, which was killing off all the silkworms of France and Italy. Till then he had hardly seen a silkworm, but he found out what was the matter with his patient. There was a microscopic parasite in him, developed from germs in the eggs, and by selecting sound eggs healthy worms could be reared. The French silk industry was saved, or would have been, "but for the unfortunate intervention of conditions of an economic order." Then a new group of patients was brought to M. Pasteur—the sheep and oxen of France, which were dying at the rate of from fifteen to twenty-five millions yearly of anthrax. It was a microscopic nuisance again, and M. Pasteur discovered his famous method of prevention by inoculation with "attenuated" microbes. This discovery, says M. Bert, is the grandest and most fruitful of all, France now vaccinates her flocks and herds wholesale. M. Pasteur has also turned his attention to the relief of the pig by vaccination.

His discovery of a preventive treatment for anthrax was preceded by a similar discovery respecting a disease which afflicts poultry, and which is known as chicken cholera. M. Pasteur is now willing to try what he can do with the cholera in human beings; and has courageously asked the Minister of Commerce to organize a scientific mission to proceed to Egypt to study the disease there under his guidance. The stimulus to discovery in other directions has not been the least important part of M. Pasteur's work, and a crowd of his followers are now experimenting to demonstrate the parasitic origin of all infectious maladies.

According to Prof. Huxley, M. Pasteur's labors alone are equal in money value to the whole 5,000,000,000 f. of indemnity paid to Germany in the late war. Yet a member of the Assembly thought it monstrous that he should receive a pension, while he was actually selling his "vaccine" at the cost price of a penny a tube.—*The Manchester Guardian.*

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending August 11, 1883, indicate that diarrhœa has increased, and that tonsillitis, intermittent fever, remittent fever, consumption, and whooping-cough have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending August 11, and since, at sixteen places, scarlet fever at eleven places, and measles at fourteen places.

OBITUARY RECORD.—The death of DR. JEAN BAPTISTE PETIT, Physician-in-Chief to the Asylum for the Insane at Nantes, Honorary President of the Association of Physicians of the lower Loire, Member of the Council of the General Association of Physicians of France, is announced. He was a pupil of the recently deceased Dr. Archambault, having pursued his first alienistic studies under his direction, and has filled the position left vacant by his death since 1854.

NOTES AND QUERIES.

HYSTERO-EPILEPSY.

To the Editor of THE MEDICAL NEWS.

SIR: In reply to the query of Dr. Jno. C. White, of New York, dated July 30, 1883, I can only state that I made careful inquiries concerning the boy afflicted with hystero-epilepsy, whether he was addicted to the habit of masturbation. I could not get the patient to acknowledge masturbating, nor did the parents have any suspicion in regard to it. Of course, I should have mentioned this fact in my article.

Allow me to call attention to THE MEDICAL NEWS, page 376, September 30, 1882, to a case of hystero-epilepsy in a boy, reported in the *Progres Medical* for August 26, 1882, in which the reporter calls especial attention to the fact that there was no history of masturbation.

I am, yours obediently,
E. J. KEMPF, M.D.

FERDINAND, IND., AUGUST 14, 1883.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 13 TO AUGUST 20, 1883.

BAXTER, JEDEDIAH H., *Chief Medical Purveyor U. S. Army.*—To proceed to San Francisco, California, *via* St. Louis, Missouri, on public business connected with the Medical Department, and on completion thereof will return to his station.—*Par. 1, S. O. 185, A. G. O., August* 11, 1883.

BARNETT, RICHARDS, *Captain and Assistant Surgeon.*—Granted leave of absence for one month on surgeon's certificate of disability.—*Par. 2, S. O. 149, Department of the East, August* 10, 1883.

BURTON, HENRY G., *Captain and Assistant Surgeon.*—Relieved from duty at Fort A. Lincoln, D. T., and assigned to duty at Fort Assinniboine, W. T.—*Par. 1, S. O. 141, Department of Dakota, August* 11, 1883.

BENHAM, R. B., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort Assinniboine, W. T., and assigned to duty at Fort A. Lincoln, D. T.—*Par. 2, S. O. 141, Department of Dakota, August* 11, 1883.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, APRIL TO JUNE 30, 1883.

BAILHACHE, P. H., *Surgeon.*—To examine officers and cadets of the Revenue Marine Service, April 2, May 28, and June 4, 1883. To proceed to New York, N. Y., to make arrangements for the care of seamen, April 30, 1883. To proceed to Chattanooga, Memphis, St. Louis, Cairo, Evansville, Louisville, Cincinnati, Gallipolis, Wheeling, and Pittsburg, as Inspector, June 23, 1883.

MILLER, T. W., *Surgeon.*—Detailed as President of Board of Examiners, May 15, 1883. Detailed as member of Board for the Physical Examination of Cadets of the Revenue Marine Service, May 15, 1883.

WYMAN, WALTER, *Surgeon.*—Detailed as member of Board for the Physical Examination of Officers and Cadets of the Revenue Marine Service, May 1, 15, and 28, 1883. Detailed as member of Board of Examiners, May 15, 1883.

MURRAY, R. D., *Surgeon.*—To proceed to Pensacola, Fla., and take charge of Quarantine Service, May 21, 1883.

GASSAWAY, J. M. *Surgeon.*—Granted leave of absence for ten days, April 21, 1883. Detailed as Recorder of Board of Examiners, May 15, 1883.

SMITH, HENRY, *Surgeon.*—Granted leave of absence for thirty days on account of sickness, June 14, 1883.

FISCHER, J. C., *Passed Assistant Surgeon.*—Detailed as member of Board for the Physical Examination of Officers of the Revenue Marine Service, May 1 and June 4, 1883.

COOKE, H. P., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, May 15, 1883.

O'CONNOR, F. J., *Assistant Surgeon.*—Relieved from duty at Detroit, Mich., and assigned to temporary duty at Boston, Mass., May 10, 1883.

GUITERAS, JOHN, *Assistant Surgeon.*—Granted leave of absence for thirty days, without pay, April 3, 1883.

ARMSTRONG, S. T., *Assistant Surgeon.*—To proceed to Memphis, Tenn., for temporary duty, May 21, 1883.

BENNET, P. H., *Assistant Surgeon.*—Granted leave of absence for thirty days, on account of sickness, June 26, 1883.

AMES, R. P. M., *Assistant Surgeon.*—Granted leave of absence for fourteen days, April 3, 1883.

DEVAN, S. C., *Assistant Surgeon.*—Detailed as medical officer of Revenue Steamer "Corwin" during cruise in Alaskan waters, April 16, 1883.

BEVAN, A. D., *Assistant Surgeon.*—To proceed to Detroit, Mich., for temporary duty, June 11, 1883.

GLENNAN, A. H., *Assistant Surgeon.*—To proceed to Norfolk, Va., for temporary duty, June 26, 1883.

APPOINTMENTS.

The following candidates, having passed the examination required by the regulations, were appointed Assistant Surgeons by the Secretary of the Treasury, June 6, 1883:

ARTHUR D. BEVAN, M.D., of Illinois, and
ARTHUR H. GLENNAN, M.D., of the District of Columbia.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIII. SATURDAY, SEPTEMBER 1, 1883. No. 9.

ORIGINAL LECTURES.

THE TREATMENT OF THE CHRONIC MYELITES.[1]

A Clinical Lecture,

BY PROF. DUJARDIN-BEAUMETZ,

MEMBER OF THE ACADEMY OF MEDICINE, PHYSICIAN TO THE HOPITAL ST. ANTOINE, PARIS, FRANCE.

GENTLEMEN: If it were incumbent on me to give the history of the diseases of the spinal marrow, this lecture would be far too long, for on no subject has so much study been spent the past few years as on these spinal inflammations. Clinical medicine and pathological anatomy, based on physiological and anatomical studies which have had the spinal marrow for their subject, have enabled us to trace not only the tableau of diseases of the spinal cord and of its membranes, taken collectively, but also the various alterations which affect the different bundles composing the medullary axis. Unhappily, therapeutics has not followed the unceasing progress of clinical study, and we are still obliged, as far as treatment is concerned, to make use of the same medicinal means heretofore employed, and which are most generally inefficacious, so that, in a great number of cases, the idea of incurability accompanies the diagnosis of affections of the spinal medulla.

Nevertheless, as the medullary diseases are frequent; as, moreover, they have a long and progressive course, and will often claim your care, I have thought best to set forth the kinds of treatment most in use, recognizing at the same time their inefficacy. This inefficacy is easily understood when you take into account, on the one hand, the position of the spinal cord, which, surrounded by its membranes, is with difficulty reached by direct treatment, and, on the other hand, the very structure of the cord, which in such small volume comprises nerve-centres and conductors, that establish a direct communication between the brain and the mixed nerves.

The least alteration in the histological integrity of the spinal axis must then profoundly modify the functions of the parts over which this portion of the cord presides, and notwithstanding that we see tumors, even of considerable size, develop without apparent symptoms in certain portions of the cerebral mass, the least disorder, scarcely appreciable to the sight, in the substance of the spinal cord, will make itself manifest by symptoms of great gravity. This fact explains why it is only since the application of histology to medicine that we have been able accurately to diagnosticate the affections of the medulla, since in most cases the pathological alterations, invisible to the naked eye, can only be studied by means of high powers.

Standing, as we do, on therapeutic ground, our study of the myelites may be considerably abridged; for, directing our attention to the processes which determine medullary diseases, therapeutics need not distinguish the different myelites which are called systematic myelites, such as sclerosis of the posterior columns, sclerosis of the lateral columns, sclerosis of the anterior cornua, which clinical medicine and pathological anatomy have described as special morbid entities. What we have really to oppose is the connective-tissue induration which produces these pathological changes, and the therapeutic means to employ are the same in sclerosis of the posterior columns, and in sclerosis of the lateral columns.

When we take a general survey of the diseases of the spinal marrow, we find that they may be referred to three principal types. In the first group are placed the different degenerations which affect the medullary axis and its envelopes (cancer, syphilis, etc.); in the second, we meet the same alterations which we have studied in the preceding chapter on apoplexy, *i.e.*, the rapid and sudden disorganizations of the spinal cord (spinal hemorrhage, spinal *ramolissement*), produced by rupture, or serious lesion of the spinal bloodvessels. These are veritable medullary apoplexies. All the alterations of the third group have for their origin a hyperæmic and inflammatory process. It is with this last group, which is the most frequent, that we are now especially concerned; and if, in the anatomo-pathological details on which I am about to enter, I seem to vary somewhat from my customary method, it is because these details have, from the standpoint of therapeutics, a preponderating importance.

Inflammation of the spinal medulla presents itself under two distinct forms: in one, the hyperæmia affects all the constituent parts of the cord, and causes their speedy disorganization; in the other, the inflammatory process, whether primitive or secondary, attacks only the connective-tissue element, determining a hyperplasia of the neuroglia, which speedily chokes out and destroys the nervous elements.

Here, then, we again meet with that great division of inflammations which we have already seen produce so much mischief in the kidneys and in the liver, and just as we have interstitial and parenchymatous nephritis and hepatitis, so also we have interstitial and parenchymatous inflammations of the spinal cord.

As for parenchymatous myelitis, I have shown in my *thèse d'agregation* on acute myelitis the march of the inflammatory process, and I have dwelt especially on the first period called the stage of tumefaction, and which results not only from the vascular hyperæmia, of which the medulla is the seat, but also from the swelling of the neuroglia and the nervous elements.

In interstitial myelitis, the neuroglia appears alone to be affected. By the organization of its cellular elements, under the influence of an indurating process, it chokes out the nerve-cells or tubes. Vulpian, in his remarkable lessons on the diseases of the spinal cord, has dwelt at great length on the pathogeny of this sclerous process, especially under the head of locomotor ataxia, and he adopts the view that the proliferation depends on primitive irritation of the nervous elements. But this is not the only opinion advanced: some, as Ordonez, maintain that the vascular alterations are the primitive cause of the sclerosis; others affirm that the hyperplasia of the neuroglia is primitive. I believe that both hypotheses are correct, and that, from a therapeutic standpoint, we ought to make a great account of them.

What can medicinal agents accomplish in cases of parenchymatous or interstitial myelitis? In parenchymatous myelitis we cannot do much, except in the period of tumefaction, and as we cannot influence either the neuroglia or the nerve-tubes, our sole action must be on the circulation of the cord. When, however, the exudation has taken place, and the medullary substance is destroyed, it will be impossible for us to repair the disorders which result from the softening. In the case of interstitial myelitis, we are impotent to arrest the hyperplasia of the neuroglia, and the disorders which are its consequence, and all that we can do is to diminish the nervous irritation which this hyperplasia determines, or the hyperæmia of which the latter is the result.

---

[1] Translated from advance sheets by E. P. Hurd, M.D., of Newburyport, Mass.

To sum up, then, our therapeutic endeavors must first be directed to combating the primary causes of the inflammation; secondly, to opposing the hyperæmia of the cord. Apart from this twofold duty, we are powerless, and the utmost that we can do is to mitigate the consequences which result from the medullary changes, and which are so detrimental. I shall briefly review the various therapeutic agents which we can employ, then make special application of them to the different spinal affections.

To fulfil the first of these indications is often easy, and in the case of myelitis by traumatism or by compression, it will be sufficient to remove the foreign body which irritates or injures the cord to cause disappearance of the resulting inflammatory symptoms. In the case of Pott's disease, with lesion of the vertebræ, special surgical appliances are necessary to remedy the spinal deformity which produces compression on the cord, and causes paralysis. In the case of syphilitic gummata and exostoses, the specific treatment will sometimes remove the inflammation and its products.

In other cases, we can do much to prevent inflammatory mischief by hygienic measures. Whether the medullary sclerosis be primitive and the result of repeated congestions of the spinal cord; whether it be secondary, from irritation of the nervous elements (Vulpian), it is not the less true that every excessive exercise of function on the part of the cord and its integral divisions may be a predisposing cause of sclerosis. Therefore, forced marches, too prolonged muscular labors, may determine veritable myelites, which are described under the name of myelitis from *strain* (*surmenage*), and which are observed in animals as well as in men. The abuse of the genital functions, and, in particular, coitus while standing, enter into the same group, and have often been invoked as the determining cause of *tabes*. You readily see, then, how much may be done by hygienic measures of prevention when once these causes are known, and I pass to the second indication, which is to combat the medullary hyperæmia.

The circulation in the spinal cord is very active; a multitude of venous and arterial vessels from numerous sources form around its bony canal and membranes a rich vascular plexus, which it is difficult for us to reach by any direct means. As, however, the spinal vessels and the vaso-motors which innervate them can be affected reflexly (vide Vulpian, *Appareil Vaso-Moteur*, t. ii. p. 49), you readily understand that by an action limited to points more or less distant from the spinal axis we may modify the circulation in the cord, and it is on this action that revulsive medication is based; a kind of treatment which is first in importance in spinal affections.

Although tradition from the dawn of medical history has affirmed the beneficial influence of energetic revulsion in diseases of the spinal cord, in our time, certain physicians have denied this favorable action, and have maintained that revulsion increases the suffering of patients without ameliorating their condition. This, gentlemen, is a mistake, and facts of experimental physiology confirm most unequivocally the results which clinical medicine has accumulated during the ages.

What, then, has experimental physiology taught us on this point? From a great number of conclusive observations, I select the following: You are all familiar with the results which Vulpian obtained in electrizing a nervous branch communicating with the intrathoracic chain of the great sympathetic; there was most marked contraction of the bloodvessels of the region of the spinal cord, from which was derived the intercostal nerve with which the nervous filament electrized was in relation. In his numerous and remarkable researches on the circulation of the spinal cord, Brown-Séquard, after tying or irritating the nerves of the kidneys or suprarenal capsules, observed a contraction of the bloodvessels of the cord on the side which was irritated. Frinberg obtained a paralysis, *a frigore*, in a hare, on spraying with ether the skin of the back which he had previously shaved. As you are well aware, on this very reflex action the theory of so-called *reflex* paralysis has been based, also of myelitis and meningomyelitis *a frigore*. Without entering into the long discussions which have arisen on this subject, it has been determined both by experiments on animals and by clinical experience, that external excitations made on the skin do modify the circulation in the spinal cord and its envelopes. Let us now examine the agencies utilized in revulsive medication in these affections. Everything has been employed, from frictions with irritant ointments to the cautery and moxa. The latter revulsives, which were till recently the most in use, are to-day being abandoned, being advantageously replaced by punctiform galvano-cauterizations. The use of caustic potash or Vienna paste is likely to be attended with certain inconveniences, and in particular, that of producing suppurating sores over the vertebral column; these last some time, and are not without danger to patients who are obliged to maintain the dorsal decubitus, and whose skin performs its functions badly by reason of trophic disturbances determined by the medullary affection.

The electrical points on the contrary, rendered so easy of management by the invention of the cautery of Paquelin, present all the advantages of energetic cauterization without the least inconvenience. Moreover, these cauterizations, which do not cause troublesome sores, may be renewed every eight days. You practise them along the spinal column, right and left of the middle line, punctiform cauterizations in parallel series, and in number varying according to the exigency of the case. These cauterizations are preferable to vesication by the cantharidal blister, for the vesicatory, besides removing the epidermis, determines trouble in micturition, a function generally more or less disturbed in diseases of the spinal cord. In certain cases the seton may be employed; this is one of the most powerful revulsives that I know of, but it is of especial utility in affections of the brain and upper portions of the spinal cord.

To the revulsive treatment we may join the application of cold, which also, as we have seen by the experiments of Frinberg, may modify the circulation in the spinal cord. But in order to obtain durable effects, it is necessary to prolong the applications of ice, and this is always inconvenient. Pulverizations of ether by the spray apparatus, if they could be continued sufficiently long, would be indicated in these cases where the physiological effect of cold is desired.

Hydrotherapy applied to the treatment of medullary affections, is a two-edged sword, which must be managed with great prudence. In fact, it does not cause anæmia of the spinal cord. In the majority of cases it congests it, and this it is which explains the successes and the aggravations which have been obtained. Successes, when one has to do with those paralyses *sine materia*, which appear in the course of neuroses, or those which have a dyscrasic origin, and which accompany diphtheria and other acute diseases, also those paraplegias observed in anæmia and chlorosis; aggravations, when the indication is to combat inflammatory and sclerous processes, for in these cases hydrotherapy, by inducing congestion of the cord, favors rather than opposes the hyperplasia of the medullary neuroglia.

To avoid these disadvantages, warm douches have been advised, or tempered douches, as Beni Barde has recommended, but it is always important when you employ either cold douches or tempered douches, to examine with care the cutaneous sensibility, often strangely perverted in patients affected with spinal diseases.

We have seen that electricity applied over the bony canal of the spinal cord modifies the medullary circulation; from this has resulted the employment of electricity in the treatment of congestions and inflammations of the cord. Two methods are in current practice. In the one you make use of faradic currents (here the portable battery does good service), and with the electric brush you make energetic revulsion along the vertebral column. I have seen happy results from this faradic treatment in tabes dorsalis. In other cases you apply galvanic currents up and down the spine; there has been much dispute about the direction of these currents, some being of opinion that ascending, others that descending, currents are preferable. I believe that the direction is a matter of little consequence, and that one may use indifferently either ascending or descending currents. To cauterizations, to applications of ice, to electricity, we must add certain internal medicaments, of which the purpose is to diminish the congestion, or the connective-tissue hyperplasia which results from it. As for certain of these medicines, their application is the result of the knowledge of their physiological properties; as for others, empiricism has led to their adoption and usage. We will pass rapidly in review the greater part of these remedies.

The curious property which ergot of rye possesses of causing contraction of the capillary network has been utilized in affections of the spine; and Brown-Séquard is one of the most strenuous partisans of this therapeutic employment of ergot. The results which I have obtained from this medicament in spinal sclerosis have not answered my expectations, and I believe that the use of ergot in these diseases is based on theoretical considerations rather than on sound clinical experience.

Ergot is given in substance or in the form of ergotine or ergotinine. The hypodermic method of administration may be adopted, injections being made over the spinal region with ergotine or ergotinine. The dose of the latter ought not to exceed two milligrammes (one-thirtieth of a grain), and one milligramme is enough for an ordinary dose.

Strychnia has been recommended in the treatment of the diseases of the spinal cord, but, as Vulpian remarks, the therapeutic action of this alkaloid having no influence on the morbid process, the cause of the paralysis, and strychnia, moreover, being incapable of removing the disorders which result from the inflammation, no curative effects can be expected from this medicament in acute or chronic spinal affections. I go further, and add, that often the action of this drug is injurious by reason of its irritating influence on the medullary axis. It is best, then, to be very chary in the use of strychnia; and even to discard it altogether in congestions of the cord, and never to use it except in the case of paralysis called essential, or *sine materia*.[1]

It has been claimed that iodide of potassium has also an action on the circulation of the spinal cord, and that it is capable of anæmiating it. I believe that the good effects which have been obtained from this medicament are not the result of the influence of the iodide on the circulation, but of its specific and resolvent action on products of a syphilitic nature. A great number of tabetic patients are syphilitic, and are therefore likely to be benefited by the iodide.

Bromide of potassium has an important *rôle* in the treatment of diseases of the spinal cord, not because it has any direct effect on the phlegmasic process acute or chronic, but because it tends to diminish the excito-motor power of the cerebro-spinal axis; the bromide, then, is indicated whenever signs of irritation or excitation of the spinal medulla supervene.

Empiricism has made great account of two medicinal agents in the treatment of medullary sclerosis, nitrate of silver and phosphorus.

Nitrate of silver was recommended for the first time in 1861, by Wunderlich,[2] but it is especially to Charcot and Vulpian that the employment and popularity of this remedy in locomotor ataxia are to be ascribed.

Nitrate of silver is given in pills of one centigramme; at first one, then two, then three, then four of these pills a day, the last dose never to be exceeded. This medication, which is only of utility after the inflammatory symptoms have subsided, may give you in some cases amelioration and even cure, if the observations reported by Wunderlich, Rosenthal, Hammond, etc., may be relied on; but it is well to bear in mind that these are exceptional cases, and for my part I have to confess that I have never obtained, even from the prolonged use of nitrate of silver, any results worth mentioning.

---

[1] Fouquier has remarked that when strychnine is given to paraplegic patients, convulsive manifestations in the paralyzed members often ensue. When the spinal cord is no longer in communication with the brain, its excito-motor power is augmented, and strychnia greatly enhances this reflex excitability. When, in a frog, you cut the spinal cord transversely, and inject strychnia, it is in the inferior members that the first effects of the poison are seen; but as Vulpian well observes, in order that this action may be produced in paraplegic persons, it is necessary that reflex excitability be preserved in the paralyzed limbs. (Vulpian, *Substances toxiques et médicamenteuses*, Paris, 1882, p. 580.)

[2] Siredy noted the good effects of bromide of potassium in a case of locomotor ataxia; effects already witnessed by Vulpian. His dose was two grammes, gradually increased to six grammes each day.

Wunderlich was the first to administer nitrate of silver in this disease. Out of five cases treated by him, in 1861, there was one recovery. The year following Charcot and Vulpian published a monograph on the subject. They administered the nitrate in pill form, one centigramme; at first two, then three, and seldom more than four pills a day. Of five cases treated by them with this remedy, there was in all great amelioration; the lightning pains disappeared, and the muscular movements gained in force and precision.

After the publication of Charcot, Moreau, then Beau reported cases of cure by nitrate of silver. In Germany, Küchenmeister reported observations in which the medicament produced no effect. In 1863, Wunderlich published in *Archiv der Heilkunde*, another memoir in which were recorded cases of amelioration and cure under medication by nitrate of silver. Rosenthal, Hammond, etc., have also noted recoveries in ataxia from nitrate of silver.

Teissier, of Lyon, after showing that the locomotor ataxia described by Duchenne, of Boulogne, and the tabes dorsalis of Romberg, are one and the same disease, is emphatic in his praises of nitrate of silver in this malady. The results are variable, sometimes there is improvement in the power of muscular coördination, sometimes only the painful manifestations are relieved.

(Wunderlich, *Archiv der Heilkunde*, 1861-1863; Charcot and Vulpian, *Bull. de Thér.*, t. 62, p. 481; Moreau de Tours, *Union Méd.*, Oct. 1862; Beau, *Bull. de Thér.*, 1863, t. 64, p. 315; Trousseau, *Bull. de Thér.*, t. 64, p. 82; Hammond, *On Diseases of the Nervous System*, p. 709; Tessier, *De l'ataxie loc. et de son traitement*, 1864.

Do not forget that the medullary sclerosis for which nitrate of silver is employed, does not progress in a uniform manner, and that it presents periods of ascension, and periods of arrest; it is easy then to understand that according to the precise time in the evolution of the disease in which the medicament is administered, amelioration or aggravation of the symptoms may be observed.

How does the remedy act? We are wholly ignorant. Does imbibition of the silver salt by the neuroglia hinder the proliferation of the latter? Does the medicine act on the nervous elements themselves? These are questions which we cannot answer.

I was the first (in 1868) to propose the use of phosphorus in locomotor ataxia.

Delpech had several years before (in 1863) applied phosphorus to the treatment of certain paralyses from chronic poisoning, and in particular to that produced by sulphide of carbon. I have continued this phosphorus medication, and, although I have never observed a cure by this remedy, I have in many instances noted an amelioration, characterized by a sensation of increase of force, and diminution of incoördination. But the same reservations which I made *à propos* of nitrate of silver, ought to be made here, and one may well ask if in many cases the amelioration obtained is not rather the consequence of the natural march of the disease than of the action of the medicine. My pupil, Dr. Eugene Lemaire, has published in his remarkable thesis on the employment of phosphorus the greater part of those observations.[1]

This phosphorus medication needs to be closely watched, and I am going to enter into certain details which appear to me to be necessary. When I commenced my experimentation with phosphorus, I immediately stumbled against a difficulty, the unreliability and the danger of the preparations in use; and I proposed to substitute for the phosphorated oil of the codex,[2] solutions of phosphorus in chloroform, of definite strength, and I also had capsules made containing one milligramme ($\frac{1}{60}$ grain) of phosphorus. But attention was awakened on this point, and thereupon successively appeared the monographs of Mehu and Vigier.

Mehu showed that while the *oleum phosphoratum* of the codex, as ordinarily prepared, is of uncertain strength, a sufficiently good solution might be had by heating the oil very hot, and henceforth unalterable capsules of phosphorated oil might be obtained, each containing one milligramme of phosphorus. Vigier, by his studies on the metallic phosphides, showed the advantage which might be derived from these preparations, and he introduced phosphide of zinc into therapeutics.[3] These capsules of phosphorated oil, and Vigier's pills of phosphide of zinc, are to-day the preparations of phosphorus most in use.

When you prescribe phosphide of zinc, do not forget that four milligrammes represent one milligramme of phosphorus. Whether you make use of granules of phosphide of zinc containing four milligrammes, or capsules of phosphorated oil containing one milligramme, you ought to observe the following rules: Commence with one pill, or one capsule, and increase gradually till ten are taken in the twenty-four hours; continue this dose three or four days, then suspend the medicine for five days, to renew the treatment by commencing with one capsule. These interruptions in the phosphorus medication are necessary in order to avoid accumulation of action, and to permit the medicine to be eliminated. In following these rules the phosphorus treatment can be continued with safety for months or for years. I add that in order to render the medicament more tolerable to the stomach, you would do well to order the phosphorus to be taken at meal time, you will then avoid in great part the eructations of *lucifer-match* taste which follow the administration of this remedy. There is another caution to be observed in prescribing phosphorus in tabes. It will not do to give it when there are any symptoms indicating any considerable degree of congestion or irritability of the nervous system, nor in the case of gastro-intestinal troubles; moreover, to get any good from the phosphorus treatment it must be continued a long time.

On what is this action of phosphorus in locomotor ataxia based? Here, as in the case of nitrate of silver, we are obliged to make hypotheses. My own theory is the following. Ranvier, in his experiment with phosphorus, has shown that when this metalloid is inserted under the skin of animals, you do not provoke inflammatory disorders, but you determine arrest of the formative and nutritive operations of the histological elements. It is possible that in the spinal cord phosphorus thus opposes the proliferation of the neuroglia; but, I repeat, this is only a hypothesis, and I give it for what it is worth.

Now that we have taken a general survey of the different modes of treating medullary affections, let us study the indications of treatment in the different forms of myelitis. I cannot here speak of all the varieties of spinal inflammation — their number is considerable. You will find in the work of Grasset a table which gives a good summary of all the kinds, and which will enable you to judge of their number. I shall only call your attention to those cases which you will oftenest be called to treat, the congestions of the spinal cord, the meningo-myelites, the myelites by compression, sclerosis of the posterior columns, disseminated sclerosis, and, in fine, that known as atrophic paralysis of infancy, or sclerosis of the anterior cornua.

The congestions of the spinal cord are frequent, and their causes are multiple; they do not generally entail anything more than a relative incapacity or paresis of the lower extremities, a paralysis in its nature curable. As in every hyperæmia, the first indication is to suppress the cause of which it is a manifestation; and whether the medullary hyperæmia depends on rheumatism, on uterine or hemorrhoidal congestion, on too prolonged dorsal decubitus, on exaggerated fatigue, or on sexual excesses, your therapeutics should be varied to meet the causal indications. Rheumatism is one of the most frequent causes of congestion of the spinal cord, and, for my part, I remember to have observed, with Dr. Lasegue, during my earlier student days, a very curious case of sudden paraplegia in a kitchen maid; it was a result of acute articular rheumatism, and disappeared when the joints became affected. In these cases you understand the utility of dry or wet cups along the spine, of steam baths, and salicylate of sodium. At other times you will have to deal with simple paralysis, *a frigore*, reflex paralysis from the impression of cold on the cutaneous surface. Here the treatment is different; besides the ordinary revulsives, such as blisters to the spinal region, you may employ sudorifics, and particularly pilocarpine, which, by the cutaneous congestion which they produce, have a favorable effect on the paralysis. Prolonged fatigue, by reason of the physiological congestion which it occasions in the spinal cord, is a factor in the etiology of this affection; here you must enjoin absolute rest, as well as revulsion. This word *rest* leads me to speak of the effect of dorsal position in the affections of the cord. Lying a long time on the back induces, as you well know, passive congestion of the spinal medulla, and it is probably to this congestion that we are to attribute the nocturnal erections which take place during sleep. You understand, then, that this fact has a certain influence in affections of the cord, and you will see patients predisposed to spinal congestion who, by reason of the dorsal decubitus of the night can scarcely support themselves on their feet in the morning. This paresis disappears after standing a short time, with disappearance of the congestion which caused it.

[2] The phosphorated oil of the codex contains two grammes (ʒss) of phosphorus to one hundred grammes (℥iij, ʒijss) of oil of sweet almonds, and is an uncertain preparation

[3] Vigier, On the Therapeutic Employment of Zinc Phosphide (*Bull. Gen. de Ther.*, t. lxxiv. p. 268).

This fact has a certain importance, and Brown-Séquard has derived from it therapeutic hints. In anæmia of the spinal cord, he directs the patient to lie on his back, while in spinal hyperæmia he is to lie prone on his belly.

Thus far I have said nothing of bloodletting, which has been much employed in affections of the spine. Very much vaunted formerly by Ollivier, who advised in these cases, besides general bleeding, leeches to be applied in great number to the dorsal region, and wet cups, this antiphlogistic treatment is to-day well-nigh abandoned. At the same time, wet and dry cupping may render considerable service in active congestions of the spinal cord, and it is a therapeutic measure not to be neglected.

Meningo-myelitis, whatever may be the cause, is one of the medullary affections the most frequently observed. It is characterized by two marked symptoms; first, by pains, often severe, coming in paroxysms, and bearing considerable resemblance to the *douleurs fulgurantes* of ataxia and to sciatic neuralgia; secondly, by impotence, more or less complete, of the inferior extremities, with conservation of sensibility, the external portions of the medullary columns being alone affected. Here energetic revulsion is indicated, preferably by cauterizations along the spine. You must also assuage the pain, for this is one of the symptoms of which the patient most complains. All the various remedial measures which I spoke of under the head of the neuralgias will have their place. Double sciaticas ought always to make you suspect meningo myelitis. But the most effectual means for allaying the pain is the subcutaneous injection of morphia, and, in fact, this alone will in many cases bring relief. You must also watch the functions of the bladder and intestines, which are often profoundly disturbed in these cases of paraplegia due to spinal disease.

As for the condition of the bowels, we have either obstinate constipation or fecal incontinence. The constipation will yield to drastic purgatives; these medicaments not only restore regular stools, but they act as revulsives and may thus modify the circulation in the cord and its membranes. In certain cases the most violent purgatives cannot overcome the constipation; this is because the rectum is paralyzed and allows itself to be distended beyond measure by fecal accumulations. Here you will have to break up the fecal mass with the finger, or scoop it out with a spoon in order to clear the rectum.

As for fecal incontinence, the most scrupulous pains must be taken for cleanliness; nothing is more important in myelitis, for trophic troubles are of common occurrence, and often, in spite of all your care, extensive bed-sores will form over the sacrum, and even around the anus, as a consequence of dorsal recumbency. In these cases the fracture-bed will render great service; it enables you readily to dress the bed-sore, and to vary the position of the patient.

The disorders which meningo-myelitis inflicts on the urinary organs are still more serious. At first the patient often experiences some tenesmus, due to spasm of the bladder, tenesmus which soon gives place to retention or to incontinence. For the retention you will be obliged to use the catheter, notwithstanding the liability to cystitis with purulent urine which it occasions. For the latter evil, and to prevent putrid absorption, it will be necessary to wash out the bladder with solutions of carbolic, boracic acids, resorcine, etc., at the same time giving internally benzoic acid, oil of sandalwood, turpentine, copaiba, boldo or buchu, which are antagonists of fermentation.

If retention of urine has inconveniences, incontinence has quite as grave; the incessant flow of urine irritates the genitals, soils the bed-clothes and the clothing, and augments causes already existing of local gangrene and erysipelatous inflammation of the skin. In the case of male patients, urinals have been perfected by the use of which they can escape these accidents, but it is not so with the paraplegic female, who must suffer all the ill consequences of the incontinence.

When the inflammatory symptoms have subsided, then much can be done to restore the power of movement to the lower extremities. Here hydrotherapy, massage, frictions, electricity, may render real service; but these measures should never be employed in the acute stage of the affection, for they would cause aggravation of the disease.

Myelitis by compression demands the same local treatment as meningo-myelitis; it demands also a special treatment directed to the removal of the cause. If the latter be cancer of the cord or its membranes, we can do nothing but alleviate pain by hypodermic injections of morphia. If it be Pott's disease, we can by an appropriate plaster jacket, as Sayre, of New York, recommends, do much toward straightening out the vertebral column, and removing the deformity which is the cause of the compression. If the cause be syphilis, nothing can be more serviceable than the injections of peptonate or albuminate of mercury, which not seldom cause the myelitis and paraplegia rapidly to disappear.

I come now to the treatment of the medullary scleroses, and especially of the typical form oftenest met with in practice, progressive locomotor ataxia. This word *progressive*, by which Duchenne characterized the pathological entity which he described, indicates the little control which therapeutics has over this morbid condition, and in so designating it, Duchenne pronounced a sentence of incurability. Since then, therapeutics has not lifted this sentence, and it is best to bear in mind that this affection is almost always above the resources of our art. Nevertheless, ataxic patients have been cured, and are now being cured; but these are exceptional cases, and despite periods of calm and respite which may last months and even years, the ataxic individual sees his disease progress slowly or by bounds.

These cases of cure concern more especially syphilitic patients. Without adopting altogether the opinion of Fournier, who will have it that all ataxic patients are syphilitic, it is nevertheless well to remember, that in a great number of cases syphilis is the cause of tabes, and when the affection is taken at the commencement, an appropriate antisyphilitic treatment may cure it. But it will not do to take for granted that it is always so; and in a great many instances in which, in syphilitic patients, there exists some form of medullary sclerosis, the most energetic and the most violent treatment will not favorably modify the march of the disease. However, the fact of syphilis coexisting with tabes dorsalis, always gives a hope and a chance for your patient, which you ought to improve.

There are neuropathies which sometimes present ataxic symptoms; these false ataxies are often completely cured by hydrotherapy, or a course of treatment at the thermal springs.

The first condition of treatment of sclerosis of the posterior columns, is to avoid all circumstances which tend to provoke congestion of the cord, a congestion which almost always precedes the hyperplasia of the neuroglia. You should then prohibit, in the case of these patients, prolonged muscular fatigue (a fatigue which is the more easily induced the more voluntary force the patient is obliged to expend in his movements); sexual intercourse ought also to be forbidden. You should also have recourse to energetic revulsion, and in particular to punctiform cauterizations along the vertebral column, and this especially when signs of irritation or congestion of the cord appear. You can also use in the periods of remission nitrate of silver or phosphorus, following, in the case of phosphorus, the rules which I have laid down. You will almost always obtain with this phosphorus medication an amelioration, more perceptible to the patient than to yourselves; he will tell you that he feels stronger, and that he has a better command of his limbs, at the same time that an examination does not disclose any real progress. I have never observed genital excitation following the administration of phosphorus, and I very much doubt the aphrodisiac properties which have been ascribed to this medicament.

The lightning pains are among the most formidable complications of the disease; here our "sheet-anchor" is hypodermic morphia, despite the fact that ataxic patients are very likely to become morphomaniacs (a great many at the present day are such). Sometimes extremes of temperature diminish notably this pain; I have lately had under my care a French engineer, who, when constructing railroads in Russia, could succeed in calming the *douleurs fulgurantes* of his disease only by surrounding his feet and legs with ice. In some patients heat has the same effect. In these cases Chapman's rubber bags for pounded ice or hot water will be useful. Nerve-stretching has been proposed for these *douleurs fulgurantes*. This elongation of the sciatic nerve, practised for the first time in Germany by Langenbuch, in 1879, in France, by Débove and Gillette, in 1880, and since repeated by Esmarch, Erlenmeyer, Sury-Bienz, Hirschfelder, Rzehaczek, has not given any definite results, and though causing a temporary amelioration, it is often accompanied by trophic disturbances of great intensity. Balneotherapy and thermal treatment have an important *rôle* in the therapeutics of ataxia. For my part, I have abandoned hydrotherapy in the treatment of medullary sclerosis. I believe that cold douches can only augment or provoke spinal congestions, and I am happy to see that most of my colleagues of the Society of Hydrology are of the same opinion.[1]

If hydrotherapy has rather inconveniences than advantages in the treatment of ataxia, it is not so with thermal treatment. Three stations claim preëminence, Neris, Balaruc, and Lamalou; the thermal establishments of the latter seem to be most efficacious in chronic myelitis.

Finally, to these balneotherapic means, we must add electricity. Onimus and Rosenthal have insisted on the curative action of continuous descending currents in the affections of the spinal cord. It is a means which you ought always to employ, without expecting always to obtain much amelioration.

On the other hand, electricity has a preponderating *rôle* in the atrophic paralysis of infants, which, as the recent researches of Roger and Damaschino and of Laborde have shown, is to be attributed to central myelitis affecting the anterior horns, and destroying the large multipolar cells of that region. These alterations have as a consequence the atrophy or destruction of important groups of muscles. Our only means of combating this disease are galvanism, gymnastics, and hydrotherapy, in a word, all those agencies which can excite nutrition in atrophied parts. These means have real efficacy only at the onset of the disease; unhappily the first periods often pass unnoticed, and it is not till the later periods of the malady that our help is demanded, and then little can be done.

The same treatment is applicable to a disease which resembles the atrophic paralysis of early childhood. I refer to progressive muscular atrophy, which in accordance with the pathological studies of the French school of medicine, and I refer particularly to the labors of Hayem, Vulpian, Troisiêr, Charcot, and Gombault, ought to be attributed, like the atrophic paralysis of early childhood, to chronic parenchymatous myelitis, localized in the anterior horns of gray substance. In these cases constant currents applied methodically may have a happy influence.

Such, gentlemen, are the principal considerations which I have to offer *à propos* of affections of the spinal cord; you will find them quite incomplete, but from a therapeutic standpoint they are necessarily so, by reason of their very incurability. These diseases of the spinal medulla, in fact, constitute the most gloomy chapter in therapeutics.

ORIGINAL ARTICLES.

A PECULIAR AFFECTION OF THE NAILS IN HEREDITARY SYPHILIS.

By ARTHUR VAN HARLINGEN, M.D.,
PROFESSOR OF SKIN DISEASES IN THE PHILADELPHIA POLYCLINIC.

The interest which attaches to every symptom of hereditary syphilis, and the importance of obtaining all possible information as to the history of individuals suspected of inherited syphilitic taint, make it desirable that each manifestation should be studied and known so far as possible. For this reason the affection of the nails which I am about to describe, merits an attention which its intrinsic importance would not perhaps demand.

Florence M., three months of age, was brought by her mother to the Polyclinic for treatment on May 30th of the current year. The history given was scanty and unsatisfactory, but evidently nothing was withheld purposely. The child's father was said to have had some well-marked general eruption of the skin six years previously, but had never shown any other sign of disease so far as his wife's knowledge went. The mother, herself, seemed to enjoy perfect health, and had never had any symptoms which could point to syphilitic disease. She had never had any miscarriages.

Débove, Gaz. des Hôp., 11 Dec. 1880. Gillette, Union Med., No. 17, Jan. 1881. Sury-Bienz, Deutsch. med. Zeitung, 1881. Du traitement de l'ataxie locomotrice (Soc. d. hydrologie Med. Séance du 4 November, 1878).

The infant was quite healthy at birth, but when not more than three weeks of age, a number of bullæ showed themselves upon the soles of the feet. These disappeared spontaneously shortly after, and later a more generalized erythematous and papular eruption began to make its appearance and spread continually up to the time the little patient was brought to the Polyclinic for treatment.

On examination the child was found to be fairly well-nourished, but fretful, with a characteristic weary-looking, aged expression, the frontal protuberances of the cranium somewhat enlarged, the lateral prominences not noticeably protuberant, the nostrils partially occluded but not showing any purulent discharge, small characteristic fissures and cicatrices at the angles of the mouth, and a number of small split-pea sized erosions or patches on the dorsum of the tongue. A well-marked eruption of a peculiar fawn color, when viewed as a whole, and made up of numerous variously sized papules covered the scalp, face, arms, thighs, legs, palms, and soles. About the buttocks these papular lesions seemed inclined to rise above the surface and become hypertrophic, with an abraded surface, forming true moist papules or what used to be called "condylomata lata."

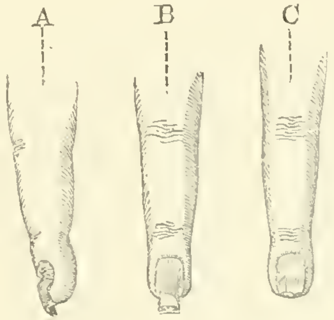
The most peculiar feature presented was, however, in the condition of the finger and toe-nails, which had all submitted to marked alteration in appearance, the result of the syphilitic disease. The child's mother was unable to say when and how this alteration in the nails had first commenced, but she remembered that nine weeks ago when the infant was not more than three weeks old the nails began to show a yellow discoloration in the centre, and to take on an arched shape as if shrinking together from the sides. The nails of the feet were affected first; later, those of the hands, and they gradually assumed the appearance shown when the child was brought for treatment.

Examination showed the nails of both fingers and toes to be alike affected, being partly curled in on their lateral edge until they occupied less than one-half or scarcely even one-third of the entire width of the nail-bed. Growing out some little distance beyond the ends of the fingers and toes the nails bent over in a claw-like shape so as to resemble the claws of a dog or other animal, a resemblance made stronger by the dark, brownish discoloration of the nails.

The sketch which I made shows the appearance presented by the nails at this time in the figures A and B of the cut; fig. C shows the appearance of the nails when gradually recovering their normal appearance under the influence of treatment.

The surface of the contracted portion was furrowed with fine transverse markings, while the proximal portion of the nail-bed from which it sprang was thrown up into rugous folds. The nail-bed alongside of the contracted nail was somewhat roughened and slightly brownish. The diseased nails were not thickened, and were not in any way misshapen, except for the perfectly uniform changes just described, which involved all the nails in precisely the same manner.

The infant was ordered daily baths, each containing ten grains of corrosive sublimate, and later was ordered one grain of iodide of potassium in water thrice daily. Under this treatment a rapid amelioration of all the symptoms ensued, the lesions of the skin soon disappeared, the nasal passages became clear, the child became more cheerful, and the deformed nails were gradually thrown off and replaced by healthy ones. By the end of a month the child was to all appearance well, excepting, of course, the entire growth of new nails, which was still in progress. The medicine, however, was ordered to be continued several months longer.



There is not very much to be said with regard to this case beyond pointing out its salient peculiarities. It is in some respects I think unique. At least I have never met with an account of a similar case. Jullien (*Traité des Mal. Vénèriennes*, p. 1009) says that the palmar and plantar skin affections, which are so common in hereditary syphilis would naturally lead to the supposition that the nails would often be involved, and such indeed is the case. In squamous onychia the nails are surrounded by a red areola, the horny layer is striated longitudinally and has a dull, tarnished look; under the microscope the epithelial layer of the bed of the nail is seen to be hypertrophied and secretes irregular horny lamina. This dry *onyxis* often gives occasion to the fall of the atrophied nail and its replacement by a new one, which at first healthy, submits progressively to the same alteration. In this connection may be mentioned the ulcerative form of onyxis sometimes met with in hereditary infantile syphilis, which does not differ essentially from that met with in the acquired syphilis of the adult. This too sometimes occurs on many fingers simultaneously.

In my case above described there was no ulcerative action around the nail, nor even any appreciable amount of onychia, it was merely a very unusual form of dry onyxis. I should add that no sign of return has shown itself, the nails have assumed for the most part a perfectly healthy appearance, and in a few months at furthest all trace of any former affection of the nails will in all probability have disappeared.

ANALYSIS OF THIRTY-THREE CASES OF HEMORRHAGIC MALARIAL FEVER,

WITH SPECIAL REFERENCE TO THE USE OF QUININE IN THIS DISEASE.

By R. D. WEBB, M.D.,
OF LIVINGSTON, ALA., EX-PRESIDENT OF THE MEDICAL ASSOCIATION OF THE STATE OF ALABAMA.

IN THE MEDICAL NEWS of July 21, 1883, my friend and colaborer, Dr. E. D. McDaniel, gives a "Condensed Tabular Report of Twenty-four Cases of Hemorrhagic Malarial Fever," the salient point of which seems to be to show the danger of the use of quinine in this disease. Believing, as I do, that the lives of those suffering from hemorrhagic malarial fever depend to a great degree upon the judicious use of quinine, here, as in all other malarial fevers, I am unwilling to let the inferences attempted to be set out by this report go unchallenged; and more so as the inferences are supplemented by such expressions as "here lies . . . the true reason why quinine is so dangerous and so uncertain a remedy;" "some of the cases in the table which died *with quinine* might possibly have lived without it, for they seemed to be doing well until a dose of quinine, given with the intent of aiding their condition, seemed to have the contrary effect, and to determine an unfavorable result."

Table I.

		Sex.		Result.		Quinine.		Recov'd.		Died.	
Cases.	Approximate Age.	Male.	Female.	Recovered.	Died.	Taken.	Not taken.	With quinine.	Without quin'e.	With quinine.	Without quin'e.

These two sentences show plainly the object of the tabular report. Without in any way entering into details of treatment, I submit the subjoined analysis of thirty-three cases of the same disease occurring in my practice from 1867 to 1874. I will follow the outline of Dr. McDaniel in giving the tabular statement.

Remarks.—These twenty-four cases were all typical cases of hemorrhagic malarial fever; they were all the cases treated by me during this time. Case No. 1 was some distance in the country. I did not see him until in the second paroxysm, and his stomach was in such condition that I was unable to give him quinine with any degree of success. I do think he was ever under its influence. At this time I had not resorted to its hypodermic use in these cases. Case No. 9 was of a most malignant type. The stomach would not retain quinine. Delirium developed in the first paroxysm, and the patient died comatose, without reaction from the second paroxysm. Case No. 24, a medical friend, was impressed with the idea that quinine was not required in these cases. At his request, and under protest, I treated him *without quinine*. The treatment was such as indicated by Dr. McDaniel and others who do not like quinine in this disease. The case was not seemingly severe, and lingered for several days. I have ever regretted that I consented, even at his own request, to treat the case without quinine.

In the twenty-four cases there were three deaths and twenty-one recoveries, or 87.5 per cent. recoveries, and 12.5 per cent. of deaths. Of these deaths, one (No. 24) was *without* the use of quinine, another (No. 1) with its unfavorable use, and the third (No. 9) was so malignant that probably no treatment would have been more successful.

In the twenty-three cases treated *with quinine*, there were two deaths, or 8.6 per cent., with twenty-one recoveries, or 91.4 per cent.

The character of the two cases resulting in death has already been given.

The one case treated without quinine died, or 100 per cent.

Table II.

		Sex.		Result.		Recovered.		Died.

Besides these twenty-four cases, I saw in consultation during the same time nine cases. As is generally known, cases seen in consultation are regarded as alarming from the outset, or they have already been under unsuccessful treatment until they assume an alarming aspect. Hence, in pernicious forms of fever of a malarial type, seen in consultation, we should naturally expect a high rate of mortality. It is hardly fair, then, to judge of the results of any plan of treatment by cases seen in consultation, and hence I have deemed it necessary to append remarks on these cases, showing why I have placed them *practically without quinine*.

---

[1] Very sparingly.

[2] Unable to retain quinine; died, without reaction, in second paroxysm.

Remarks.—It will be seen from an inspection of this table that the two recoveries were under the use of quinine. In one of these cases (No. 7), spirits of turpentine had been used in conjunction with the quinine; in the other (No. 9), the hæmaturia seemed to be much increased on first giving the quinine; but the next paroxysm was arrested, and with the cessation of the fever the hæmaturia also ceased, and the patient soon convalesced; and here, I may remark, seems to be the basis of the fear of quinine in these cases. Quinine will undoubtedly, in a certain number of these cases, increase the hæmaturia, and sometimes even seems to cause it. Seeing this, the timid administrator stops his quinine, and his patient dies, with the quinine under the ban of killing him; whereas, with a bolder hand, directed by a proper idea of the true cause of this *symptom* (a disturbance of the vaso-motor system under malarial influences), he would have unhesitatingly continued it, and his patient might have had a good chance to live. Remove the cause of the disease, and the hæmaturia will cease. I have seen quite a number of cases to which this remark applies; some, in which the quinine, given at the expiration of the second hebdominal period as a prophylactic measure (a measure familiar to all physicians in malarial districts), caused a return of a decided hæmaturia, without fever. In these cases I have not hesitated to repeat the quinine the next day, with the best results. Here the timid hand, not appreciating the true nature of the disease, and led from the true point of attack by the *symptom* of hæmaturia, falters, and his patient suffers the result. No. 8—here we have one death *with quinine*. This is not to be wondered at. In all forms of pernicious malarial fever (and this may be ranked among the worst), we may expect deaths under any plan of treatment, and whoever is so unfortunate as to meet with a number of these cases must be prepared for its victims.

The remaining six cases died *practically without quinine*. No. 1, an old lady treated in 1867, when calomel was much relied on, died of exhaustion, without ever having been well under its influence, her physician waiting for the fever to abate under the use of calomel, febrifuges, and baths, before commencing the quinine. No. 2, a most malignant case, died in the first paroxysm, without reaction from the depression of the initial chill. No. 3, an intemperate man, also died during the first hæmaturic paroxysm, and before I reached him as consulting physician. No. 4, a very malignant case, in which the patient refused his quinine, and died in a state of delirium in forty-eight hours. No. 5 got no quinine until seen by me on third day of attack, and died that night. No. 6, a railroad employé, without any of the surroundings necessary to successful treatment, and not seen by his physician until too late to do any good by any course of treatment; seen by me just before death. No. 8 died, under the use of quinine, with suppression of urine. Nos. 7 and 9 recovered, as already stated, with quinine.

So far, then, as these thirty-three cases go, quinine is shown to be not a *very dangerous*, or even *uncertain*, remedy. In the twenty-three cases where it had a fair trial, we have 91.4 per cent. of recoveries, and only 8.6 per cent of deaths, a rate of mortality which is not excessive in a pernicious fever; and in the two cases which make up the 8.6 per cent. of deaths, there were extenuating circumstances.

The death-rate, which is high, in the nine cases seen in consultation has been already explained, so as to show that it is, at least, *not due to the use of quinine*.

But I am reminded that figures, which are said "never to lie," contradict each other in the tables of Dr. McDaniel and those introduced in this article. Very true, an unfortunate fact it is that these unerring digits are so easily made to reflect, to some extent, the mind of him who uses them. The *environments* and the *method* of giving the quinine in the ten fatal cases in the two tables of Dr. McDaniel are not given, and how much of this result is due to these, and not to the quinine, cannot be known without them.

The positive result of six recoveries in the six cases *treated without quinine* is of more value; but, while it teaches us that cases may and do recover under this plan of treatment, it does not follow that other plans are necessarily wrong. Notably, among other plans of treatment claimed to be successful, is the use of atropia hypodermically, by Dr. W. C. Jackson, of Montgomery. He says, "I use no other remedy to counteract this condition, and relying solely and entirely upon this Sampson, it has never failed me." Believing, with Dr. Jackson, that atropia acts powerfully upon the vaso-motor system, I should feel disposed to supplement the quinine by atropia; but it will require a much wider field of observation than the few cases treated by Dr. McDaniel *without quinine*, and by Dr. Jackson *with atropia alone*, before we may feel justified in discarding quinine in this disease, which is confessedly malarial and paroxysmal.

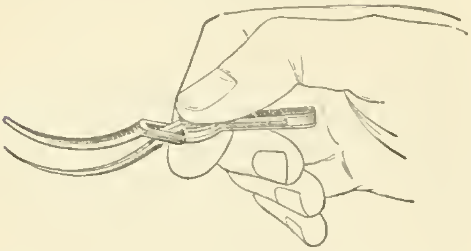
ACUPRESSURE FORCEPS:

AN INSTRUMENT FOR THE INSTANTANEOUS ARREST OF HEMORRHAGE DURING SURGICAL OPERATIONS.

By OSCAR H. ALLIS, M.D.,
SURGEON TO THE PRESBYTERIAN HOSPITAL; LECTURER ON ORTHOPÆDIC SURGERY AND JOINT DISEASES IN THE POST-GRADUATE COURSE AT JEFFERSON MEDICAL COLLEGE; SURGEON TO THE JEFFERSON MEDICAL COLLEGE HOSPITAL.

Under this heading, I wish to introduce an instrument to the medical profession that I have devised for the arrest of hemorrhage. It consists of two blades, Fig. 1, under the command of a spring, the lower of which is a needle, and designed to transfix bleeding tissues, which done, the grasp of the hand is released, and compression is instantly effected between the blunt blade which lies upon the surface of the bleeding vessels and the needle which lies beneath them.

FIG. 1.

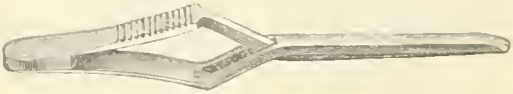


Its special application is where hemorrhage takes place simultaneously from many bleeding vessels. Few surgeons have not felt the need of a certain and instantaneous hæmostatic in operations in which the tourniquet cannot be used, or after the tourniquet has been removed. In the latter case, though the main vessels have been ligated, the hemorrhage is often so great from numerous small bleeding points, and the usual means of arrest and ligation so tardy, that fatal collapse has not infrequently resulted.

It is for this class of cases that the acupressure forceps have been devised. Beneath a bleeding area the needle is thrust, and the spring, instantly denoting that the hemorrhage has been arrested, leaves the operator to turn his attention to another point of danger. Thus half a dozen instruments will be found as efficient and much more transparent than a corps of assistants—not getting in the operator's way, and maintaining a silent but effective grip until the ligature may be applied, and the instruments one by one removed. In the surgical clinics of medical colleges, in hospitals, in active military service, and in the private practice of those surgeons who cannot command adequate assistance, this instrument will, I believe, be found of great service.

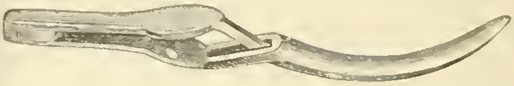
As acupressure forceps, they often render the ligature unnecessary, for no oozing will follow their removal if the vessels are small, and their application has continued for several minutes. In operating upon the female perineum, in which the ligature is to be avoided, this instrument especially (No. 2) will do excellent work.

FIG. 2.



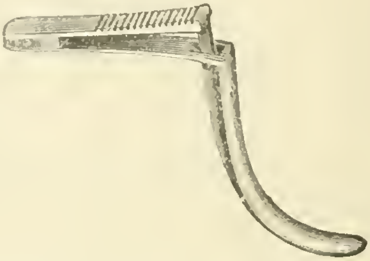
Four varieties and nine sizes are made. One, in which both blades are needles—a suggestion of Dr. Keen, is not represented by a cut. All the diagrams are full size. Nos. 2 and 3 will be found most generally useful. No. 2 or a larger size will be found effectual in deep wounds, as in lithotomy. For plastic operations upon the face, a small size is made (Fig. 1). There are three sizes of No. 2, and three of No. 3—the largest of which is fully eight inches long.

FIG. 3.



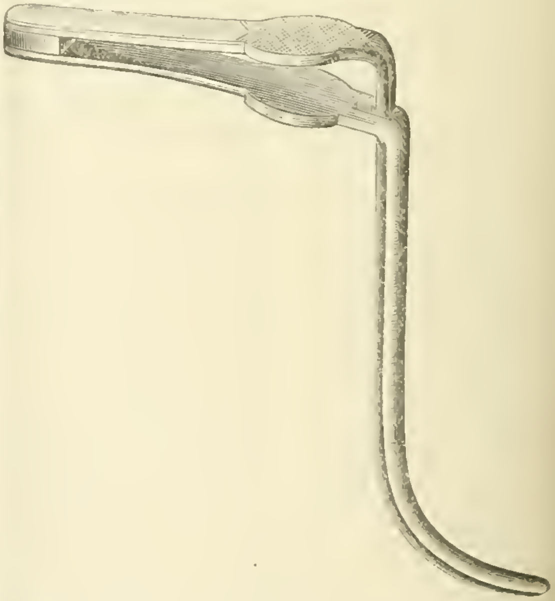
Although each instrument may be used not only as a hæmostatic, but also as a tenaculum, yet the two designed especially as tenacula are represented in 4 and 5. For this purpose, I have found the large size (Fig. 5) to work admirably. In using the instruments, a quick, firm thrust is necessary, but this manœuvre can easily be acquired on the coatsleeve.

FIG. 4.



My preference (if I could have but one variety) is for No. 2. Were I ordering a dozen, I should take three of No. 2, three of No. 3—two of each a size larger, one of No. 5, and one of mammoth No. 3. No. 5 is not necessary if an ordinary tenaculum is at hand, but I believe that those having No. 5 will set the old tenaculum aside.

FIG. 5.



I have given these instruments a satisfactory trial in the Jefferson Medical College clinic and hospital and in the Presbyterian Hospital, and feel that they have a useful future before them.

They have been made with great care by Mr. E. A. Yarnall, 115 South Tenth Street, of this city, who has spared no pains to make them perfect in every respect.

Philadelphia, 1604 Spruce Street.

HOSPITAL NOTES.

AN AFTERNOON IN THE OUT-PATIENT ROOM, MIDDLESEX HOSPITAL, LONDON.

Service of A. PEARCE GOULD, F.R.C.S. Eng.,
ASSISTANT SURGEON TO THE HOSPITAL.

INGROWING TOENAIL.

This young woman, gentlemen, tells us she has a sore great toe from wearing tight boots, and you now see she has what is wrongly called an "ingrowing nail." It is not the nail that is at fault, but the skin on the side of the nail has been pushed over the nail until a foul ulcer has been produced. It is very generally seen on the outer side of the nail; but, you remember, lately we had a case occurring on the inner side. You have seen me remove a portion of the nail in many cases; but this case, which is not very severe, we shall probably be able to cure by stuffing a piece of lint carefully under the nail, so as to raise it, and at the same time push aside the overgrowing flesh. She must also wear square-toed boots.

LACTEAL CALCULUS.

This woman is a nursing mother. The left breast is soft, normal in all respects, with an excellent nipple. The right mamma is about four times as large, with distended veins coursing over it; it is firm, heavy, but the skin is still pale. The areola, too, is full, and as I compress the breast gently, you can see the individual "sacculi," or dilatations of the galactophorous ducts, swelling under the thin skin of the areola, and at the same time some milk flows from the nipple. She tells us that she was quite well till three days ago, since when she has not been able to suckle with that breast, owing to its causing pain, and the breast has been steadily swelling ever since. She has shooting and hot pains in the breast from time to time. It is an excellent example of *milk congestion* of the whole mamma, the same condition which usually precedes a lacteal abscess of an individual lobe, and if left unrelieved in this case might run on to suppuration of the entire gland. Let us find the cause. The nipple is a typically good one; there is no "crack" in it; but at its summit is what looks like a small pustule, and is very tender. I open that with a knife, and, instead of pus, a small, solid, oval body, a *lacteal calculus*, escapes. This has obstructed the outlet of one of the ducts, the swelling around has obstructed others, and the pain in the act of suckling has prevented her relieving the remaining lobes, but all the while secretion has been actively going on, and from time to time specially stimulated by the nursing at the other breast. A little bathing of the nipple with hot water completes the surgical treatment, and all that is wanted now is to put the child to this breast alone for the next one to three times that she nurses.

SUPRAMAMMARY ABSCESS.

Here is quite a different case. This young girl is seventeen years old, and has menstruated regularly for two years, the last time three weeks ago. The outer side of the left areola is swollen and reddish in color; skin is shiny and œdematous, and there is superficial fluctuation. The mamma itself is unaffected. In the left axilla are two enlarged tender glands. This then is an areolar or supramammary abscess, a form often seen at, and soon after, puberty, and apparently associated in many cases with the active development of the part at that time. This patient traces the mischief to a blow. The house surgeon will open the abscess by an incision radiating from the nipple to avoid the ducts, and she will speedily be well. Remember the enlarged glands; they are always found in mammary abscess.

PHLEBOLITH.

This woman tells us that in April last she had a "gumma" behind the knee, which was treated by painting it with iodine. It left only a little lump behind. A few days ago she stumbled, and since then has felt pain in the part, and she wants to know if her trouble is returning. Feel the part. You will notice a hard narrow body, about two and a half inches long, a little tortuous in outline, and about the size of a small crow-quill, freely movable laterally, placed across the tendon of the semitendinosus muscle, just above the knee; trace it up, and you will notice a dilated vein just above. Clearly, then, she had a thrombus in a dilated vein in April. This thrombus has organized, and then become calcareous, and now forms what is called a phlebolith. In its organization it has contracted, and now moves freely in the bed which the previously enlarged vein had made for itself. It calls for no treatment; it is a permanent possession of the woman. We will simply tell her so, and advise her to rest the leg if at any time it pains her. The so-called "gumma," then, in this case, was what goes by the name of "phlebitis."

TWO CASES OF HUNTERIAN CHANCRE ON THE LIP.

Look well at these two women. Here is a chaste woman, thirty years of age, who all her life has been subject to a crack in the middle of the lower lip; two months ago the edges of the crack began to swell. She has now a distinct induration of the middle of the lip, with slight abrasion of the mucous surface. Under the jaw you will find a number of hard, enlarged, freely movable, and quite isolated lymphatic glands. Just below the occiput are two similar glands. On the left tonsil is a small superficial ulcer, and over the body are two or three small dusky papules.

The other patient is a woman of the town, who, six weeks ago, was under our treatment for gonorrhæal rheumatism of the right knee. Four weeks ago she came with a sore on the upper lip, just to the right of the middle line; its surface looked aphthous, but there was no other spot like it, and the base was a little hard. The induration increased, and is now very marked, while the surface has cleared, and is merely abraded. She has enlarged glands under the jaw, like the last patient, and all over the trunk she has an abundant eruption, which first came out three days ago. She says she has no sore throat; but there is a superficial, ragged, gray ulcer occupying half the free surface of the left tonsil. They are both taking mercury in pill—at first four grains of blue pill a day, then six grains. We will now increase the dose to eight grains. For the throat ulceration we will prescribe a bicyanide of mercury gargle, ½ gr.-℥j, and a little white precipitate ointment for the surface of the chancres. The prognosis depends chiefly upon the faithfulness and perseverance with which they will carry out the treatment, which will consist in a long course of mercury, at no time severe enough to do more than just touch the gums. Of course, we warn them against infecting others by kissing, or the common use of spoons, etc.

NÆVUS OF SCALP.

Here are two infants brought to show us the result of treatment. This one had a subcutaneous nævus on the forehead just in front of the hair. I treated it by constant pressure, and to secure that I applied, as you have often seen me do, *contractile* collodion, painting it on layer over layer twice a day; in this way very firm pressure has been kept up for some weeks. You see the result, the collodion scab has been off a month; the nævus is quite cured and there is no scar nor any other indication of the late presence of the vascular growth. This little body had a capillary nævus over the parietal bone, and I burnt it with a fine-pointed cautery in four places. The growth is quite stopped, and the few capillaries which are not cured may be left, probably they will undergo a slow process of obliteration; if not, we can treat them in a similar manner later on. Now we will call in some male patients.

HYDROCELE OF TUNICA VAGINALIS.

This young man, aged twenty-four, makes the diagnosis for us, for he tells us that two years ago a swelling in the scrotum was tapped and fluid was drawn off. The swelling has gradually reappeared. We see the tumor is limited to the scrotum, as you grasp the upper part of the scrotum there is nothing but the cord between the finger and thumb; the swelling fluctuates, is dimly translucent, and the testicle is embedded in it, though it can be felt at the lower and back part of it. Notice his age; we must not be content with tapping the hydrocele; we must endeavor to obtain a radical cure, and for this purpose we will, after tapping, inject some pure carbolic acid.

HYDROCELE OF CORD: OMENTAL HERNIA.

This lad is seventeen years old. At first sight this case resembles the last, but examine it carefully. There is a tumor filling the left side of the scrotum, fluctuating, clearly translucent in all its parts, with a slight impulse on coughing when he stands up—none on lying down. Further, the testicle is not enveloped in the swelling, but is quite at the bottom of the scrotum below the hydrocele, and gliding freely over it. The cord too is very much thickened and indurated. The fluid is evidently contained in the unobliterated funicular sheath of peritoneum, and in such cases there is often a fine communication with the peritoneal cavity, so we will lay him down and try whether the tumor is reducible by long-continued compression. No, it is not. I will now tap it. You see I have drawn off several ounces of the ordinary straw-colored hydrocele fluid. But notice that what we took to be a thickened cord is now felt to be an irreducible omental hernia; and now we see the explanation of the curious symptoms. The cyst pushed up the omentum and fixed it in the inguinal canal and just outside the ring, here it felt like a thickened cord, and when the man coughed the impulse in the hernia was transmitted to the hydrocele.

EPITHELIOMA OF TONGUE.

This man is forty years old, and comes to us complaining of a sore tongue which he has noticed for two months, and which pains him very much on eating. He is a plumber by trade, says he has enjoyed perfect health, denies ever having had any venereal disease, and by cross-questioning, you see that I do not obtain any evidence of his having had constitutional syphilis. About midway along the right edge of the tongue is a small depressed, irregular ulcer, with raised, uneven, and hard edges; the rest of the tongue is perfectly healthy; no enlarged glands beneath the jaw; teeth not jagged. Here the diagnosis plainly rests between a late syphilitic ulcer and epithelioma, because the tongue is otherwise quite healthy, shows no signs of old fissures or papules, and because there is no history of syphilis: also, because the ulcer is very irregular, has indurated edges and base. I believe it to be epitheliomatous. The man's age and the position of the sore harmonize with this view. Notice, that while the quite healthy condition of the rest of the tongue supports this opinion, had we found the tongue in an ichthyotic condition, that also would have favored the diagnosis of cancer. We will, however, give him 30 grs. of iodide of potassium a day for a week. If it fail to have any effect, we will take the man into the hospital and excise one-half of the tongue. The method I should adopt in such a case would be to split the tongue along the middle line and cut out the one half quite far back with scissors, picking up the arteries as they are divided.

ABSCESS OF LOBULE OF EAR.

This young fellow tells us that for many years he has had a small "core" in the lobule of the right ear; it has given him no trouble till three days ago, when it rapidly swelled. Now, you see, he has a lump the size of a cherry projecting from the back of the lobule; it is soft and fluctuating. The diagnosis rests between hæmatoma and abscess. A grooved needle settles the point, for pus flows along the groove, and I will now open the abscess freely. Here, then, we may say that we have an example of what Sir James Paget has called "residual abscesses," that is, an abscess set up around (possibly in part by) a residue or remnant of some long-past inflammation.

SEBACEOUS AND DERMOID CYSTS OF SCALP.

This middle-aged man came last week with a common sebaceous cyst on the scalp. You remember that I transfixed it, and tore out the thin cyst-wall, and, after all bleeding had stopped, I painted the edges over with iodoform, dissolved in collodion, 10 per cent. The little wound is now nearly healed. In this case, the sac consisted of a distended sebaceous gland, fibrous tissue, lined by squamous epithelium, and the contents were only inspissated sebum. Now look at this young man who wants advice about a tumor just behind his left ear, which has been there as long as he can remember, and in exactly its present state. It gives him no trouble; it fluctuates, and at first sight it resembles that in the other man; but notice that the skin moves freely over the tumor, and further that a rim of bone is felt around the base of the tumor—two important differences. Here we have a congenital or dermoid cyst of the scalp. It is caused by an infolding of a portion of the epiblast of the embryo; it lies *under* the scalp, not *in* it; the sac consists of true skin, with all its special structures—hairs, glands, muscles—and its contents are *all the excreta* of the skin—hairs, epidermis, sweat, sebum. These are most often met with near the orbit. We will not treat it, as it is not causing any inconvenience. The only treatment justifiable would be complete excision of the cyst, and you must be very careful, indeed, to remove every portion of the sac. As a rule, such dermoid cysts merely rest upon the bone; occasionally the bone is depressed beneath them, and, as a still more unusual condition, the bone is actually perforated here, and thus, when you remove the tumor, you actually open the cranial cavity. Now, in this particular case, we can feel a bony rim around the tumor; so the bone is evidently hollowed out; but there is no evidence (pulsation, etc.) of perforation of the skull.

ANAL ABSCESS.

This man says he has "piles." Let us look. At a glance you see he has not "piles." Here is a superficial swelling behind the anus, reaching just over on to the coccyx, fluctuating and painful. You see I can press my finger into each ischio-rectal fossa without causing any pain or meeting with any resistance. This then is an anal abscess, the pus is just under the skin at the verge of the anus and *not* in the ischio-rectal fossa. If left to itself it will form a fistula. We will try to prevent that by making a free incision into it. Abscesses like this are the common starting-point of fistula in ano. Such fistulæ are superficial to the sphincter muscle, and in slitting them up the muscle is not cut.

MEDICAL PROGRESS.

Œdema of the Ary-epiglottic Folds, especially in Chronic Laryngeal Affections.—M. Gougenheim draws the following conclusions at the close of a memoir on this subject: 1. Œdema of the ary-epiglottic folds, especially in chronic laryngeal affections, is not always accompanied by dyspnœa. 2. When dysphagia is absent, which is rarely the case, the œdema may be latent, and is only revealed by laryngoscopic examination. 3. On laryngoscopic examination the œdematous or hypertrophied folds do not touch during the respiratory act. 4. When the patient is told to articulate the tumefied folds approach each other, but do not cause dyspnœa, and dyspnœa is only caused when the act is prolonged. 5. When the folds are very much enlarged and in contact, they are more or less completely immovable and inspiration does not cause dyspnœa, though articulation and prolonged examination produce spasm and dyspnœa very rapidly. 6. In the course of a very pronounced case of œdema of the folds, laryngoscopic examination made at the time of an attack of suffocation enabled him to see that, so far from the folds approaching each other at the moment of inspiration, they separated, though very slightly. The suffocative feeling and dyspnœa were not, then, the result of an approach of the folds to each other, but of a spasm of the cords, probably induced to some degree by the prolonged examination. 7. Sestier's theory, therefore, of these cases of dyspnœa is inexact. 8. The attacks of suffocation and the inspiratory whistling are due, in these cases, only to an intercurrent spasm, either of reflex origin or produced by compression of the recurrent laryngeal nerves. 9. The discovery of ary-epiglottic swellings is not a therapeutic indication for tracheotomy, unless there is dyspnœa. 10. It is necessary, in any therapeutic procedure, to touch the tumefied folds only with the greatest circumspection, lest a severe spasm be produced. 11. The spasm is not always, in these cases, an absolute indication for tracheotomy; Gougenheim has seen it disappear rapidly in some cases under the use of external and internal remedies. 12. When one sees the signs of laryngeal suffocation, which physicians almost always attribute to an œdema of the folds, a laryngoscopic examination should be made, if possible, as it may reveal the existence of subglottic lesions which may influence the mode of treatment.—*Gaz. Méd. de Paris*, July 14, 1883.

New Method for Determining the Percentage of Fat in Milk.—At the meeting of the Boston Society for Medical Observation on May 7th, Dr. Harrington read a paper on this subject. Attention was called to the Feser lactoscope, a small instrument designed to determine rapidly the percentage of fat in milk, and on account of its great simplicity peculiarly adapted for domestic use. The principle of the instrument depends on the fact that the more fat there is in the milk the more opaque the fluid becomes. The instrument consists of a cylinder of glass, into the end of which is fitted a stopper carrying a small rod of white glass on which some black lines are marked. A small quantity of milk (four c.c.) is now poured into the upper end of the cylinder, and water is added in small quantities until the black lines can be seen on the glass rod; the contents of the cylinder are shaken from time to time as the water is added in order to mix it thoroughly with the milk, and when the black lines can be seen the percentage of fat can be read off at once from a scale on the side of the cylinder at the level of the diluted milk. Dr. Harrington stated that he had made a number of comparative tests between this instrument and other methods, and had found that it gave very satisfactory results.

The reader said that good milk should have from two and one-half to three per cent. of fat. Some analyses of human milk have been recently published in which the results of different observers have been tabulated. From this it appears that the average percentage of fat in human milk is about two and one-half per cent., but the analyses vary so much that the results of any one man can hardly be taken as reliable.

Dr. Haven said that he had used the Feser's instrument at the West End Nursery with very satisfactory results. It shows a very great variation between different cans of milk as supplied by the same milkman, the variation being from two and one-fourth to four and one-half per cent. of fat, and he had found it much better to have the milkman mix the contents of all the cans together before bringing them to the city rather than to try to get the supply from any one cow, for in this way the percentage of fat would be the same in the milk supplied to all the children, and much more accurate observations could be made on the comparative results of feeding than where the variation between the milk for the different children was so great as under the plan of separate cans. Where the percentage is reduced below the normal it is likely to be a source of inanition, but where the fat is unduly increased it gives rise to intestinal trouble on account of a lack of the proper amount of pancreatic juice to properly digest it. It was not thought that the coloring matters used to doctor milk would interfere with the use of this instrument, for although they might affect the color of the milk they would not change its opacity to any very great extent.—*Boston Med. and Surg. Journal*, August 16, 1883.

Faradization of the Abdomen in Ascites.—In the Russian literature of the past three years, several cases have been recorded in which ascites was successfully treated by faradization of the abdomen. Skibnewski has recently reported two additional cases; the first, a little girl, æt. 9, very anæmic and with marked ascites. The urine was small, with no albumen, lungs sound, heart-beat normal, with a feeble systolic souffle. For ten days the patient took digitalis and iron without any diuretic effect, and during these ten days the circumference of the abdomen sensibly increased. The digitalis was then discontinued, the iron being kept up, and Skibnewski commenced faradization of the abdominal muscles two or three times a day. Each *séance* lasted fifteen or twenty minutes. The currents were sufficiently strong to produce muscular contraction. During the same *séance* each muscle was made to contract fifteen or twenty times. After twelve days the circumference of the abdomen was reduced from 36½ inches to 30; the quantity of urine was considerably increased. After three weeks the circumference of the abdomen was only 24 inches, and the quantity of urine normal. A month and a half after leaving the hospital, the patient had a return of the ascites. As before, medication had practically no effect, and faradization was resorted to, with the former effect.

The second case was that of a young man, æt. 17.

Ascites and augmentation of the spleen commenced after an infectious disease. The urine was small, and contained no albumen. Faradization was performed twice a day for fifteen days, and then thrice a day until, within four weeks, a cure was effected, both of the ascites and splenic enlargement.—*Revue des Sc. Méd.*, July, 1883.

Glycerine in Acute Fevers.—Semmola recommends the following drink in acute fevers: Glycerine f℥j; citric or tartaric acid grs. xxx; water Oj. From fʒv to f℥j should be taken every hour. Glycerine is useful as a combustible aliment and serves to prevent the waste of the body. With this scope it is more convenient than alcohol, which is to be feared from its exciting action on the brain.—*London Medical Record*, July 15, 1883.

Nephrectomy.—The first nephrectomy in Naples and the fifth in Italy, has been performed by D'Antona, for pyonephrosis, the lumbar incision being used. He first resected nearly two inches of the eleventh rib and carried his incision down just in front of the twelfth rib. By this measure he obtained more room for his hand. No sutures were used, but the wound was left to heal by granulation. The result was favorable.—*Centralbl. f. Chirurg.*, No. 31, 1883 (from *Riv. Clin. dell Univ. di Napoli*, No. 1, 1883).

Molluscum Contagiosum Giganteum.—Under this name Dr. S. Laache, of the Anatomico-Pathological Institute of Christiana, describes, in a recent number of the *Nordiskt Mediciniskt Arkiv*, a tumor extirpated from the nape of the neck of a female aged fifty-six. This tumor, which had lasted for thirty years, but had increased considerably for the last four years, was of the size of the fist, with nodulations or unequal protuberances on the surface; it was covered at its base with normal skin, sending tongue-like ramifications over the whole tumor, and which were transformed at last into a delicate membrane, half pellicular and half granular, covering the whole mass, except at the summit, where there was a flat, crateriform depression. Under this incomplete covering there was the mass of the tumor, which, as it were, undulated against the surface. The cut surface, equally composed of nuclei of unequal size, separated by septa of cellular tissue, presented a granular aspect, but without the knife being covered with adipose matters. Examined by the microscope, the lobules contained, in the circumference, cellules evidently resembling epidermis, while in the centre was seen a considerable quantity of corpuscles with an adipose or waxy lustre strongly resembling amyloid tissue. In all other respects they resembled the corpuscles of molluscum, with which the author compared them. In his remarks on the case, Dr. Laache discusses the differential diagnosis between molluscum and epithelioma or cancroid, to which last the tumor was at first referred. From cancroid, however, the molluscum in question was distinguished by its definite form and its tendency to grow outward, besides by its being covered entirely by a kind of delicate skin without any apparent ulceration. It was, however, the presence in considerable quantity of corpuscles of molluscum which determined the diagnosis. The author admits, however, that, as regards prognosis, the tumor could not be regarded as being so benignant as ordinary molluscum, and he therefore thinks he ought to consider it as a transitional form between the malignant epithelial tumor and the benignant one. He observes that there was no relapse at the end of more than six months. In conclusion, Dr. Laache considers the presence of nuclei in several of the shining corpuscles as a proof in favor of the opinion that the corpuscles of molluscum are the results of a peculiar degeneration of preëxistent epidermic cellules.—*Med. Times and Gaz.*, Aug. 11, 1883.

Hydrobromate of Quinine.—Dr. Garcia, of Brazil, states that malarial fever is promptly arrested by the hypodermatic injection of grs. iij of hydrobromate of quinine. This remedy possesses the advantage of causing no inflammation or nodules after subcutaneous injection.—*L'Indipendente*, July 25, 1883.

Physiological Action of Coffee.—In the course of some recent experiments on this subject, Dr. J. A. Fort, of Rio de Janerio, tested the action of coffee by 1. Completely abstaining from it for fifteen days; 2. Taking excessively large quantities for fifteen days; and 3. Taking two cups a day for twenty-five days. He concludes that coffee acts on the organs and functions by exciting the cerebro-spinal and central nervous system. Taken in very large doses, it produces insomnia by excitation of the brain. By exciting the cord, it produces muscular cramps, pains in the stomach, intestinal and cardiac troubles. The excitation which it produces in the cord is, consequently, one of a reflex or excito-motor kind. It may be such that it equally affects the nerve-roots of the sympathetic and those of the spinal nerves. It is well known that a slight excitation of the sympathetic affects the vaso-motor nerves; but if this excitation is very strong, the irritation of the vaso-motor nerves causes paralysis of them. Dr. Fort asks if this phenomenon does not explain the troubles of intestinal secretion, and the genital troubles produced by the ingestion of large quantities of coffee. Taken in moderate quantities, coffee produces a less excitation in the nervous system. It slightly stimulates the brain, causing less inclination to sleep, and increased activity of the brain. It also slightly stimulates the spinal cord, giving it tone, and slightly increasing the activity of its various functions. It is true that coffee increases tissue waste, but only by its action on the nervous system, and it causes neither a greater nor less consumption of nitrogenous food. In therapeutics, therefore, it should be classed among the reflex excitors, and not among the agents modifying nutrition.—*Bull. Gén. de Thérap.*, June 30, 1883.

Laparotomy for Tumors of the Fallopian Tubes.—Dr. A. Martin reports eight cases of laparotomy for tumors of the Fallopian tubes. Of these, five were cases of hydrosalpinx, two of which were double, pyosalpinx in two cases; and one case of double hæmatosalpinx. In arriving at the diagnosis in the cases, Martin anæsthetized the patients, and examined both per vaginam and per rectum, and in some cases through the dilated urethra. Of the eight cases only one died, from sepsis in a case of double hydrosalpinx. The pelvic cavity was entered by a long incision in the linea alba.—*Centralbl. f. Chirurg.*, No. 24, 1883.

Treatment of Vascular Tumors Without Operation.—Floriani has recently treated six cases of telangiectasis with sublimate collodion (3:20). The collodion is put on in four layers by means of a camel's-hair brush, each layer being allowed to dry thoroughly before the next is applied. On the fourth day the edges are raised and a second series of four applications are made, this being repeated every fourth day until the swelling disappears and the edges are depressed. After the crust falls off the place seems depressed and reddened, but soon resumes its normal color. This treatment is painless and requires only one or two months to cause an angiomatous tumor to disappear.—*Allgem. Wein. med. Zeit.*, No. 32, 1883.

Chloride of Lead as a Disinfectant.—Chloride of lead is now proposed as a disinfectant. It was suggested by Dr. Goolden many years ago. Half a drachm of nitrate of lead is dissolved in a little hot water and mixed with a slight excess, say two drachms, of common salt in a pail of water. The clear liquid, consisting, of course, of chloride of lead, is no doubt, an excellent disinfectant, but we do not see that it is better in any respect than chloride of zinc, which is very much cheaper. These metallic disinfectants have the advantage of being powerful deodorizers as well as germ-killers. Each will absorb sulphuretted hydrogen and ammonia, to take two typical gases, and yet neither has any smell of its own. Carbolic acid, a most valuable antiseptic, does not destroy, but only masks foul smells and leaves its own disagreeable and persistent odor in addition. Lead salts, besides being expensive, are blackened by sulphuretted hydrogen, which is a disadvantage. The only objections to chloride of zinc are that, being non-volatile, it does not purify air, and that having no odor there is constant danger of its being taken internally by mistake. This objection applies, of course, equally to chloride of lead.—*Lancet*, August 11, 1883.

Variation and Disappearance of Cardiac Murmurs.—Mr. E. Hyla Greves says, in a recent paper in the *Liverpool Medico-Chirurgical Journal*, July, 1883, that it is a matter of daily observation that certain cardiac murmurs dependent on definite organic lesions change and vary, and by no means infrequently disappear, the lesion still remaining.

There have been several cases in the Royal Infirmary during the past winter illustrating the fact, that not only may murmurs due to incurable cardiac diseases vary and even disappear, but a fact also equally important, viz., that many murmurs, apparently due to an incurable lesion, may actually depend upon lesions which are perfectly curable, and in which, therefore, the murmur may not only disappear, but also the condition of the heart which gave rise to it, and the heart itself again become perfectly normal.

It is now an undisputed fact that, even after a considerable degree of regurgitation, either through the mitral or tricuspid valves, complete restoration to the normal condition of these valves may actually take place; and the same may be affirmed, but to a much more limited extent, of the aortic valve, for the physical conditions present at this orifice naturally offer insurmountable difficulties to the process of restoration. Whether this restoration to the normal condition becomes permanent or not depends upon a variety of circumstances, more especially on the original cause of the lesion, the age, occupation, and mode of life of the patient, and in forming a prognosis these factors must be carefully borne in mind. There is a general consensus of opinion that in cases of anæmia, chlorosis, etc., as well as in general febrile conditions, there are muscular relaxation and general debility, and it is argued with great probability that the muscular substance of the heart is affected in a like manner, for after death in these cases it has been found flabby and relaxed, and in well-marked cases of chlorosis, even dilated (from loss of its elasticity), and somewhat hypertrophied. And it is probable that the so-called functional or hæmic murmurs so constantly heard in chlorosis, etc., are due not merely to the spanæmic condition of the blood, as was formerly taught, but to actual regurgitation, brought about by the relaxed and dilated condition of the heart itself, due to malnutrition. These cardiac hæmic murmurs are always systolic in rhythm, and their position of maximum intensity is about one inch and a half to the left of the pulmonary area, and in the same plane, *i. e.*, just over the position of the left auricular appendix. And, in connection with this fact, it is interesting to note that, as Skoda first observed, a mitral regurgitant murmur is occasionally heard only in this area. Naunyn attributes this to the better conduction of the murmur along the course of the regurgitating blood. This view is supported by Balfour and others. The fact, too, that the pulmonary second sound is accentuated in cases of chlorosis, indicates increased tension in the pulmonary artery, and is consequently another proof of the regurgitant origin of these hæmic murmurs. Now, inasmuch as this relaxed and dilated condition of the heart is a curable one, if not too far advanced, it follows that under appropriate treatment not only will the heart be restored to its natural condition, but also that the accompanying murmurs will disappear.

Mr. Greves gives the details of four cases in which murmurs had disappeared, and draws the following *résumé:*

Although murmurs are among the most constant of the physical signs of heart disease, still their presence does not necessarily indicate the existence of incurable lesions, nor their absence that such lesions are not present. In forming a correct diagnosis and prognosis of any case, therefore, too much reliance must not be placed on the presence or absence of murmurs, as is too frequently the case, but other signs and symptoms must receive careful examination and consideration, for often on them alone is it possible to found a correct diagnosis.

The presystolic murmur of mitral stenosis, the most typical of all murmurs, occasionally disappears, the lesion still remaining. Mitral regurgitant murmurs, when due to simple relaxation of the heart's muscle, and dilatation of its cavities and orifices, as in chlorosis and general febrile conditions, in most cases completely disappear under appropriate treatment.

Tricuspid regurgitation is occasionally a temporary condition, due to bronchitis, etc., and when the cause is removed, this condition is recovered from, as is indicated by the disappearance of the murmurs.

Aortic systolic murmurs, due to a permanent lesion at the aortic orifice, may undergo changes in their intensity, but never completely disappear.

Aortic diastolic murmurs in certain extremely rare cases have been known to disappear. In these cases a systolic aortic bruit is always present, which remains persistent, and thus indicates the existence of the lesion.

Pulmonary systolic murmurs are persistent when due to an organic lesion; but, if non-organic, may disappear temporarily or permanently.

Resection of the Wrist by Two Lateral Incisions.—M. Polaillon recently presented to the Société de Médecine, the resected bones from the wrist of a woman, æt 39, on account of a non-malignant tumor of the right wrist. The specimen consisted of the carpal bones, the extremities of the radius and ulna, and the upper extremity of all the metacarpals except the metacarpal of the thumb. The technique of the operation was as follows: After anæsthetizing the patient and applying the Esmarch bandage, he made two incisions along the radial and cubital side of the wrist. Through these openings the carpal bones, which were bathed in pus, were easily enucleated. Then about three-fifths of an inch of the lower end of the ulna were resected, and afterward the lower end of the radius was also resected. The upper extremities of the four metacarpal bones were denuded of articular cartilage, and found in a suppurating condition, and were resected with Liston's pincers for about four-tenths of an inch. All the tendons were carefully spared. The cavity was then rid of its fungosities by means of a blunt curette, and thoroughly washed with a twenty per cent. solution of carbolic acid. Metallic sutures were put in, with drainage-tubes and Lister dressing. The hand and forearm were immobilized. There was immediate union, except at one point in the radial incision, which remained fistulous for some time, and discharged small spiculæ of bone. Ten months after the operation M. Palaillon presented the patient to the Society. The hand is very useful, and its efficiency in performing various duties is improving rapidly.—*L'Union Méd.*, July 22, 1883.

PERCHLORIDE OF IRON IN SKIN DISEASES.—DR. CASARINI states that the external employment of chloride of iron is highly useful in many chronic diseases of the skin, employed as an ointment consisting of one, two, or three parts to thirty of lard, or as a lotion mixed with two or three parts of water. The diseases in which it is most efficacious are subacute and chronic psoriasis, eczematous lichen, and eczema—after all acute symptoms have subsided. From the cases he has employed it in he draws these conclusions: 1. The perchloride is a highly efficacious remedy in the treatment of simple and hemorrhagic purpura. 2. It is very useful in the chloro-anæmic condition which often accompanies certain skin diseases, such as rupia, ecthyma, and impetigo. 3. It is employed externally with promptly efficacious results for ulcers dependent on scrofula or constitutional syphilis. 4. Used as an ointment, it modifies in a most efficacious manner the squamous skin diseases, and especially psoriasis.—*Med. Times and Gaz.*, Aug. 11, 1883.

STATISTICS OF OPERATIONS FOR LYMPHOMATA COLLI.—G. KRISCH gives the results of ninety-two operations for tuberculous glands of the neck. Total number operated upon 92; complete recovery in 32 cases—35 per cent.; partial recovery in 44—48 per cent., of which there was recurrence in 22 cases—24 per cent., and general disease followed in 22 cases—24 per cent., $4\frac{1}{3}$ per cent. having phthisis. Sixteen patients or 17 per cent. died, $3\frac{1}{4}$ per cent. from the operation and $13\frac{3}{4}$ per cent. from tuberculosis. Of the patients 45 were males, and 47 females. The majority of the patients were aged from 6 to 20 years, 30 being between 16 and 20 years of age. None of the patients were over 30 years old.—*Centralbl. für Chirurg.*, No. 31, 1883.

PAPAYOTIN IN DIPHTHERIA.—DR. CRONER at a late meeting of the Verein für Innere Medicin, reported a case of diphtheria which he treated very successfully with papayotin. The attack was a severe one, in a boy, with extensive deposition of membrane and pronounced general symptoms; the sensorium being affected, and the morning temperature reaching 104° F. The throat was painted every hour with a four per cent. solution of papayotin, and in five hours the membrane was reduced to a sort of loose network, which soon disappeared. The temperature at the same time fell from 104.9° to 102° F., and convalescence progressed without any return of the membrane. Other members of the Society reported similar cases, although one or two had seen but small results from the drug; but the mass of evidence was in favor of its being at least as efficacious as, if not more so than, the forms of treatment already in use.—*Lond. Med. Rec.*, July, 1883.

EXTRACT OF CALABAR BEAN IN DIARRHŒA.—DR. MASCHKA, of Carlsbad, has found the extract of Calabar bean very serviceable in intestinal catarrh, diarrhœa, atony of the ailmentary canal, etc., and explains his views of its mode of action. The physiological action of Calabar bean, Dr. Maschka states, is upon the muscular coat of the intestines, producing contraction thereof. In acute catarrh of the intestines, it controls the hyperæmia of the mucous membrane, and arrests the excessive secretion. Under its continued use the calibre of the intestine becomes narrow, while its contents are held back or only partially expelled. In cases of habitual atony of the muscular coat, it produces a normal evacuation of the contents of the bowels. Dr. Maschka gives it the preference over preparations of opium, as its continued use does not produce the injurious effects of the latter. Although the author has not much experience of the use of this drug with children, he argues *à priori* that it has a great advantage over opium in their case, as being free from the dangers that attend the administration of opium to children.—*London Med. Record*, July, 1883.

RESECTION OF THE LUNG IN ITALY.—This operation was performed on July 6, by PROF. RUGGI, on a woman, æt. 30, for a vast phthisical cavity of the right lobe. The entire lobe was removed through an opening in the anterior superior wall of the thorax. The second and third ribs were excised for a distance of nearly three inches, the pleura opened and detached from the lung, without the least respiratory or circulatory trouble. The operation lasted about one hour and a half. Though the pulse, respiration, and temperature remained normal for thirty hours, the patient sank and died in a few days.

FOURTH CASE OF DIVULSION OF THE PYLORUS.—PROF. LORETA performed his fourth case of divulsion of the pylorus on July 12th, for pyloric stenosis. There were no untoward after-symptoms, and the patient was practically well on the tenth day.

SALICYLIC PASTE.—LASSAR recommends a paste for the skin in cases in which ointments are not borne, and more particularly recommends a salicylic paste in eczema. The advantage of the paste over ointment is its porosity. The formula is ℞ Acidi salicylici, 2 parts; vaselin, 50; zinci oxidi, amyli, āā 25; M.; leniter terendo fiat pasta.—*London Med. Record*, July, 1883.

THE SECOND GASTROSTOMY IN ITALY.—DR. FRANCESCO SUPERNO, of Pondidera, has resected the pylorus of a man æt. 43, who for ten months had suffered from gastric carcinoma. Fifty sutures were put in. The patient died of peritonitis on the third day. The autopsy showed union by first intention throughout the wound, and no blood nor feces had escaped into the peritoneal cavity.

CORROSIVE SUBLIMATE IN DIPHTHERIA.—KAULICH, believing diphtheria to be due to an organism, selects corrosive sublimate as the best germicide to treat this disease. He washes the false membranes of the mouth, nose, and throat with a $\frac{1}{20}$ to $\frac{1}{10}$ per cent. solution. In children who had undergone tracheotomy, the trachea was washed with the same solution. The application was made four times a day, or sometimes even every two hours. Inhalations of a solution of only .005 per 1,000 were used for fifteen minutes every hour or at more extended intervals. Internally, he administers to children from 1 to 2 centigrammes (= about $\frac{1}{6}$ to $\frac{1}{3}$ grain) of the drug daily in albuminous water, to which a little cognac and sugar have been added.—*London Med. Record*, July, 1883.

THE FIRST OVARIOTOMY IN SMYRNA.—The first ovariotomy in Smyrna was performed in May by DR. VILTORE BELLELI, at the Rothschild Hospital, in a woman 45 years of age. In spite of very unfavorable symptoms the woman recovered.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, SEPTEMBER 1, 1883.

NEW TESTS FOR SUGAR—INDIGO.

IN our last issue we gave an account of the new picric acid test for sugar in urine, suggested by Dr. Johnson.

Another test recently recalled to the attention of the profession by Dr. George Olliver (*Lancet*, May 19) is *indigo*. It will be remembered that when this intensely blue substance is associated with glucose, it is colorless, as is the case in nature, where, in the juice of the indigo plant, the indigo is combined with indiglucin, a saccharine substance. Reasoning from this fact, Dr. Olliver thought the color of indigo should be discharged by the glucose in diabetic urine, and upon trial found this to be the case. Mehu had also announced, in 1880, that when the carmine of indigo or the sulphindigotate of sodium is heated with carbonate of sodium and a solution of glucose, the blue color is converted gradually into green, then into red, and finally into yellow. A solution prepared by adding to a solution of sulphindigotate of sodium, carbonate of sodium, and redissolving the minutely divided precipitate by heat, possesses a greenish-blue tint, and, according to Dr. Olliver, forms a reliable, sensitive, stable; and non-caustic test for sugar. But Dr. Olliver prefers to use test-papers, which are little pieces of filtering paper about an inch long and one-quarter wide, impregnated with the constituents of the test. One of the papers is dropped into an ordinary half-inch test-tube, and enough water added to just cover its upper end. The indigo is then dissolved out of the paper, and one drop only of the suspected urine is allowed to fall into the tube, and heat applied. If sufficient sugar be present, shortly after the first simmer, a beautiful violet tint spreads throughout the bright-blue solution; very quickly this deepens, and passes into purple, this into reddish purple, which gives place to various tints of red, orange-red, orange, and, finally, straw yellow, which remains without further change, though heated ever so long. On shaking the tube, the colors return in the reverse order to that in which they appeared, terminating in the original blue. The shaking permits the more ready access of oxygen of the air to the fluid. The same change takes place in a longer time on standing. Boiling again removes the color, which again returns on exposure, and thus the alternation may be kept up indefinitely.

Dr. Olliver does not give precise directions how to make these test-papers, but they are prepared by Wilson & Sons, pharmaceutical chemists, Harrogate. We have used them, and find that the blue color is reduced by diabetic urines containing such an amount of glucose that five or six drops are required to produce a distinct reaction with a cubic centimetre of Fehling's solution. We did not, however, obtain the play of colors described by Dr. Olliver. The purple was caught, but was soon replaced by the light yellow. In another instance, where eight drops were necessary to produce the first response with a cubic centimetre of Fehling's solution, but where a cubic centimetre of urine appeared to decompose all of the copper, as much as two drachms of urine were added to the indigo solution without obtaining any reaction whatever. This same urine showed a beautiful reaction with picric acid by Dr. Johnson's method. When it is remembered that a single drop of diabetic urine will often discharge the color from a whole cubic centimetre of Fehling's solution, it is evident that the urines with which we experimented were not highly charged with sugar. At the same time, as tried by them, the indigo test-papers were found less delicate than either the copper or picric acid test. But we would not, on this account, condemn the indigo test, which has not been fully elaborated. Experiments have just been commenced with it. Our own are open to objection, being confined to the use of the imported test-papers, which may have been impaired by age. Dr. Olliver claims for it great delicacy—such that whenever one drop of the urine gave no reaction with the test, Fehling gave no precipitate, and where, with various urines, a deep violet tint would appear on the addition of the second, third, fourth, fifth, sixth, or more drops, Fehling's solution gave either negative results, or was doubtful. He is, moreover, inclined to believe that when urines which give the well-known yellowish-green reactions with Fehling's solution fail to give any response with the indigo, they are not due to sugar, and when they do respond with indigo, even in producing the first purple tinge, sugar is the responsible constituent, although he admits that normal urine gives a distinct violet after the fifth or sixth drop, which he ascribes to normal sugar. We shall have something to say at some future time with regard to normal sugar, the existence of which in urine we are inclined to doubt.

It will be seen that our own experience does not confirm this view of the extreme delicacy of the indigo, but for the reasons named, we do not desire this view to be final. We trust, our readers may be induced to try the new reagent, for it is only by the experience of numerous careful observers that the truth can be arrived at.

It is claimed, too, that this test is not interfered with by albumen, blood, pus, bile, uric acid, or the alkaline sulphides, which are common in stale albuminous urines.

THE SEWAGE QUESTION IN PARIS.

It is a mistake to believe that the question of the sewerage of Paris has been definitely and satisfactorily settled. On the contrary, the important problem of providing a proper system of sewerage has been pending for many years, and of late has been brought into special prominence by the publication of the results of the investigations of a Commission of Inquiry appointed in 1880 by the Minister of Agriculture, etc.

As originally designed, the Paris sewers were not intended to carry off anything but surface water, but they have gradually been brought into requisition for other uses, and it is now estimated that at least one-half of the sewage of the city, both solid and liquid, finds its way into these conduits.

There are two systems of sewage disposal for the city. The older one, now partly in use, depends on cesspools mostly located under the houses. In the more modern system an upright canister-shaped metal holder is used to receive the excreta, and provision is made for the escape of the liquids into the sewers. It is these systems that have proved unsatisfactory, and all are agreed that "permanent cesspools, as forming a structural portion of the dwelling, should be superseded." But the manner in which this is to be accomplished is the knotty point over which, at the present time, there is much controversy.

Two very different plans have been proposed as a substitute for the present imperfect systems: the one by the Commission of Inquiry, and the other by the City Engineers. The Commissioners recommend a modified separate system consisting of iron reservoirs and a continuous line of metallic piping, which it is proposed to lay in the sewers already constructed, and specially designed to carry off the solids to the suburban chemical works for utilization. The City Engineers firmly adhere to the plan of direct and immediate delivery of all sewage from the house, by means of a hydraulic siphon, into the sewers, and thence to the pumping stations, with plenty of water as a vehicle. This scheme contemplates the final closing of extramural sewage utilization works; the complete abolition of permanent cesspools, of ventilator shafts, and of cesspool emptying; the increase of the water-supply per inhabitant, and the final disposal of the sewage by spreading it upon the land of the peninsula of Gennevilliers.

The scheme of the Commission of Inquiry, which is not unlike the Lienur pneumatic process, except in some minor details, is opposed on account of the enormous outlay required to put it in successful operation. It is estimated that at least 600 miles of piping will be required, and, in addition, at least 230,000 soil-pipes, together with the necessary reservoirs. M. Durand Claye's estimate of the cost of the entire work, including that part of the system of sewers which awaits completion, is placed at £6,000,000. It is also urged as an objection, that the frequent emptying of the iron cesspools carried on in the public streets, although proposed to be done by suction, will, in some part of the process, necessitate direct communication with the outer air, and be productive of a serious nuisance. On account of insufficient gradients, pumping stations will be required here and there in the midst of populous districts; and it is further alleged that the scheme will require the retention, in the outskirts of the city, of poudrette works, which, it is maintained, are nuisances, in spite of every attempt to render them inoffensive in character.

In opposition to the municipal scheme it is contended that the sewers cannot be made water-tight; that the gradients are insufficient for the kind of work required; that the addition of the fecal matter of the population to the sewage will cause unwholesome effluvia; and that the germs of diseases conveyed in the sewage will not be destroyed by the plan of irrigation.

The city engineers disprove the allegation that sewers cannot be made water-tight by a reference to the experience in connection with such works in the city of Paris itself, where it has rarely happened that any leakage has occurred in the sewers, even from those which have been exposed to pressure. It is admitted, that a few miles of sewers (70) have insufficient gradients, and not unfrequently, on this account, become obstructed and give rise to foul exhalations; but these defects are not sufficiently serious to condemn the whole system, nor such as cannot be easily remedied.

As a thorough ventilation of the sewers by direct communication with the air above ground, is part of the scheme of the Board of Engineers, this proposition has been condemned on the assumption that the result will be a serious deterioration of the air of the streets. This objection has but little weight if dependence be placed in the results of a series of analytical tests recently applied by M. Wurtz, of Paris. Assuming that the sewers are properly constructed, it has been proved that the free admission and circulation of air from above ground not only dilutes and disperses noxious admixtures, but actually destroys them by chemical action.

With regard to the plan proposed by the Municipal Engineers, which contemplates the direct delivery of both solids and liquids into the sewer, and the disuse of filter tanks and separators, and the discontinuance of the old cesspool system, it may be said that it is exceedingly simple and trifling in cost, compared with the scheme advanced by the Government Commission. It is urged, that while it may not be a perfect system, it is, considering all circumstances, the most rational one to adopt; and if, after a fair trial, the dangers and objections to it are verified by practical experience, it will then be not too late to substitute the separate system of metallic piping, commended by the Commission.

One result may be predicted almost with certainty as the outcome of the present agitation of the subject; namely, that before long, Paris will be provided with an improved system of sewage-removal, that whether the one or the other of the above-mentioned plans be adopted (both of which are intended to supersede permanent cesspools and the storage of excreta upon the premises), the results will be of the greatest advantage to the comfort and health of the citizens of Paris.

THE TREATMENT OF HEMORRHAGIC MALARIAL FEVER.

We publish in the current number an analysis of thirty-three cases of hemorrhagic malarial fever, with special reference to the use of quinine, by Dr. R. D. Webb, of Alabama. A comparison of his results with those of Dr. E. D. McDaniel, related in our issue of July 21st, will prove instructive. Both of these gentlemen reside and practise in the heart of the hemorrhagic malarial district, and both are men of large experience. Dr. McDaniel speaks of quinine as a "dangerous and uncertain remedy," and as "determining an unfavorable result." Dr. Webb regards it with great favor.

Dr. McDaniel narrates eighteen cases, of which twelve were treated with quinine, and six without. Of the twelve cases treated with quinine, seven, or 58.33 per cent., recovered, and five died; of the six treated without quinine, all recovered. Dr. Webb saw thirty-three cases, of which nine were in consultation. Of these, twenty-six were treated with quinine, and seven without. Of the former, twenty-three, or eighty per cent., recovered, and three died. Of the latter, all died.

Thus it will be seen that in Dr. McDaniel's experience no cases treated with quinine recovered, and in Dr. Webb's, none treated without quinine recovered. Statistics are proverbially unsatisfactory, but these results are, at first thought, confounding. In such an important matter as this, however, one is inclined to look below the surface, and seek an answer to the question, "Had I hemorrhagic malarial fever, would I prefer to be treated with quinine or without it?" Such an examination cannot fail to discover the following: In the first place this disease is acknowledged by all, including Dr. McDaniel, to be malarial in origin, for which, at some period of the disease, quinine is generally acknowledged to be a suitable remedy.

Again, although it is true that all of Dr. McDaniels' cases treated without quinine recovered, more than half (59.33 per cent.) of those treated with quinine also recovered, and it does not follow that if those which recovered without quinine had been treated with it, they would have died. Further, if we sum up the cases of both writers, it will be noted that out of fifty-one cases in all, thirty-eight were treated with quinine and thirteen without. Of the former, thirty recovered and eight died. Of the latter, thirteen treated without quinine, seven died and six recovered. So that from either point of view the result seems to be in favor of a quinine treatment.

YELLOW FEVER.

The origin of the outbreak of yellow fever at the Pensacola Navy Yard is thus far very obscure, but a court of inquiry on the subject has been ordered by the Navy Department, at the request of the Commandant of the Yard, and no doubt every effort will be made to trace it. Surgeon Owen died on the 22d, and on the same day two suspicious cases were reported on Palofox wharf in Pensacola. They were at once transferred to the quarantine hospital, and the house from which they were removed was burned. Soon after their removal one of the cases died, and Surgeon Murray of the Marine-Hospital Service, decided from the post-mortem that it was not a case of yellow fever, but one of pernicious hemorrhagic malarial fever. In this opinion he was sustained by several physicians, but others disagreed, and the true nature of the case is still somewhat uncertain, although it seems probable that Surgeon Murray's opinion is the correct one.

No additional cases are reported in the town, and only two or three at the Yard, and the panic among the inhabitants is subsiding. A house to house inspection of the city has been made, and no suspicious cases reported.

The rumors of a case at New Orleans appear to be without foundation, and there seems little reason to fear any extended epidemic in the United States this year.

The cholera mortality is steadily diminishing, and the disease has not extended beyond Egypt. At the present writing, it looks as if M. Fauvel's prediction at the Academie de Médecine is likely to be fulfilled, and that the sudden and severe epidemic of 1883 within a week or two will have ceased.

We congratulate our friends of the New Code on the announcement of the Kansas City College of Medicine, which is "designed to fully meet the wants of an age tired of the dogmas and pathys of an obsolete past." The faculty "is composed of gentlemen of culture from every school and system of medicine that is now recognized by its merits," and includes a professor of "homœopathic therapeutics," etc., and a "professor of allopathic theory and practice." It has a faculty composed of fourteen professors and a board of directors numbering eleven. Of the eleven directors, nine are also members of the faculty.

The announcement before us, which is the second annual one, contains a list of eighteen matriculates at its first session, that of 1882–83. Of these eighteen, eleven received *ad-eundem* degrees at the end of the session, and seven were graduated. These facts speak for themselves, and we respectfully call the attention of the secretaries of the State boards of health and other licensing bodies to them.

Apropos of the above, we have recently had placed in our hands a letter from a teacher in a Southern medical college who, having heard through a friend that a gentleman intended to study medicine, writes to present the claims of "the medical centre of the South and West, the healthiest large city in America—beyond the reach of yellow fever," etc. Good board for little more than half of what it can be had for elsewhere, and railroad tickets at half rate, owing to a local fair, are among the inducements. He concludes by saying that he is allowed a certain number of beneficiaries, and will take as one the gentleman written to and charge him only fifty dollars, instead of eighty.

What indeed are we coming to? This prize-gift spirit of enterprise, worthy of a third-rate business, deserves to be mentioned only to receive from the profession the severe condemnation it merits.

SPECIAL ARTICLE.

CHOLERA DISINFECTION: ALSO, TYPHOID.

The existence of a cholera germ—a microbe, or an organized ferment, capable of indefinite multiplication—is one of the facts not susceptible of demonstration, but is rendered in a high degree probable by the mode of propagation and the clinical characteristics of cholera. That the cholera germ is contained in the excreta, and that it diffuses widely through air and water, but not more rapidly than the rate of human communication, are also facts attested by a vast number of well-directed observations. It follows, therefore, that cholera disinfection includes the treatment of the excreta coming from the sick with cholera, and the purification of air and water, the chief media by which the germ or poison is introduced into the human organism.

The agents capable of destroying germs in dejections outside of the body are very numerous, since it is not necessary to exclude the most powerful. Hence, we are not confined to the use of germicides which have proved to be most effective in the body. The problem to be solved in the disinfection of cholera excreta is—what agents are at the same time most destructive, most available, and least expensive? Fire stands first. When clothing, bedding, carpets, and similar articles are soiled by cholera discharges, no treatment is so thorough as burning them. When suitable ovens are available, an efficient means of disinfection is heat, of intensity just short of injury to the fabric. As such facilities are rare, the treatment to be applied consists of boiling water, steam, and such gases as will be mentioned presently under the head of aerial disinfection. The importance of avoiding soiling the bedding, clothing, carpets, and other cotton, linen, or woollen fabrics is very great, since such articles do much to retain, preserve from injury, and promote the diffusion of cholera germs. All who have had to do with cholera patients, know how difficult it is to secure the reception of the dejections in suitable vessels; but it should be done as far as practicable, and the disinfection should be carried out at once. As the rule of action should be *tuto cito et jucunde*, the material of disinfection ought to be kept in readiness, and the discharge, whether by vomit or stool, treated at once. Any satisfactory (*jucunde*) disinfection of such materials can be effected only by the abundant, rather lavish, application of the agent employed, so that every particle of matter and part of the vessel containing it be directly acted on.

It has been quite clearly shown that the corrosive chloride of mercury, is the most effective germicide, *per se:* in other words, that no agent brought in contact with the germs themselves, so certainly kills them; but when the sole object is to destroy, there are more destructive agents available. Nevertheless, there being conclusive evidence of its germicide power, a saturated solution of corrosive sublimate may be used with confidence. According to the description of the *United States Pharmacopœia* (1880) it is "soluble in sixteen parts of water and in three parts of alcohol at 59° F." Now, as alcohol has very decided germicide property, a solution of corrosive sublimate in common high wine, or unrectified whiskey, will be more effective than one in water merely. In a gallon of high wine, can be dissolved about one pound of corrosive sublimate, or in any quantity of high wine, corrosive sublimate may be dissolved to the point of saturation, and a tablespoonful of the solution will suffice for each dejection.

Very destructive, and comparatively inexpensive, is a solution of chloride of zinc. This can be readily prepared by dissolving zinc cuttings, or common zinc, in commercial hydrochloric acid. It can be used in this form or be further diluted by the addition of water. The official liquor zinci chloridi (*Pharmacopœia*, 1880) contains one hundred and seventy grains of the chloride to the fluidounce, and this is used for disinfection by mixing a pint of the solution with four gallons of water. The saturated solution prepared as above described, extemporaneously, is more powerful and may be diluted in the proportion of a pint to two or three or four gallons of water. Thus largely diluted it is suitable for the treatment of cesspools, or waterclosets into which the cholera discharges have been thrown, but for a destructive action on the germs in vomit or stool, the undiluted solutions—one, two, or three tablespoonfuls according to quantity—are decidedly preferable.

Next to the chlorides above mentioned are certain metallic sulphates—of iron, zinc, and copper. The most effective of these is the cheapest—sulphate of iron. In the form of commercial copperas, either as powder or in solution, sulphate of iron may be very freely employed without risk. As it is soluble in cold water in the proportion of one to two, this is the measure of strength suitable for disinfection. In the case of liquid dejections a handful of finely pulverized copperas may be added, and as it is inexpensive need not be spared. For the closet, a saturated solution—a pound to a quart of water—and for the cesspool, ten pounds to a bucketful of water will prove effective if used daily during the existence of a cholera epidemic. Saturated solutions of zinc and copper are much more expensive, and probably less effective than the copperas.

These metallic disinfectants are without odor, and hence to the uninstructed may seem inefficient, for in the minds of many the destruction of germs of putrefaction and of disease consists in the production of an ill smell, or the substitution of one foul odor for another. The most notable antiseptics are those which give forth some unpleasant fumes or vapors. The most important of these are members of the phenol group. Common or impure carbolic acid, undiluted, or mixed with some absorbent, is the favorite at present; but although fatal to some minute organisms, it is not equally injurious to all. If used for the disinfectant treatment of cholera discharges, one or two tablespoonfuls should be added to each, whether by vomit or stool. For the cesspool or water-closet into which such evacuations are emptied, the metallic chlorides and sulphates above described are better. The quantity of undiluted carbolic acid recommended for the destruction of cholera germs in the discharges may seem excessive, but, by careful examination, it will be found that the proportion of the disinfectant to the volume of fluid-matter is little more than five per cent. The various derivatives and congeners of carbolic acid are rather less efficient and more expensive. Amongst these may be mentioned salicylic acid, resorcin, thymol, etc. Various other disinfectants are available for the same kind of treatment, as chlorinated lime, iodine, bromine, chloral, but they are less efficient, less easily managed, and more expensive than those already discussed. It cannot be too strongly insisted on that all cholera evacuations should be acted on by the disinfectant selected for this purpose, as soon as passed, and after the vessels are emptied, they should be thoroughly washed with a sufficient quantity of the agent undiluted, or in a saturated solution. When no longer required, such vessels should be broken up and buried with some chlorinated lime, or subjected to high heat in an oven. Wooden close stools retain in their crevices the dried excreta, and are afterwards sources of infection: they should be burned, or subjected to a sufficiently high temperature.

What shall be done with cholera discharges in the homes of the poor, in country places where human ordure is cast on the ground, and in all those houses inhabited by people too ignorant to appreciate the character and source of the danger which menaces them, or too poor or too mean to supply themselves with the material of disinfection? In cities and towns, provided with an efficient health administration, the ignorant and the parsimonious are compelled to carry out the measures of protection necessary. But there are vast stretches of territory and considerable populations, to whom all hygienic precautions are unknown, and from whom, a cholera epidemic appearing, not even the simplest means of prevention can be expected. Cholera dejections soil the bedding, the carpets, floors, furniture, and are thrown out on the ground at any convenient point. What opinion, soever, we may have of Pettenkofer's theories, it can hardly be denied, we think, that the surface-water (*grundwasser*) is an important agency in promoting the diffusion of the cholera poison. To cast out on the ground, or in shallow pits, the dejections, is to insure contamination of the surface-water, and afterwards the general water supply. Such is an important source of contamination of the water supplies to great cities. The question for solution is, how to prevent the contamination of the ground-water when cholera prevails in outlying villages and country places, unprovided with methods of disinfection? What cheap and readily applied disinfectants are available? The principal resource is in absorbent material. Dry earth, sifted to remove coarse particles, acts well and can be used freely. The vomit and stools thus treated should not be cast out on the ground, but be placed in tight barrels away from houses, or thrown into pits dug in coarse sand or gravel, remote from water-courses. If placed in barrels the contents can be poured into suitable pits after some weeks or months, and the barrels burned. Contaminated clothing, too useful to be destroyed, can be disinfected most cheaply by exposing the articles to sulphurous acid fumes, as hereinafter described, or by subjecting them to sufficient dry or moist heat.

As the air is often the carrier of cholera germs, it is necessary to employ measures for its purification during the existence of the epidemic. Cholera matter containing the mysterious germs, dried and pulverized, readily floats in the air and lodging in the mouth and fauces, reaches the stomach with food and drink. The problem of aerial disinfection, although simple in its terms, is most difficult of satisfactory solution. As germs in the air can be acted on only by gases or vapors, the agents are few in number, and the results obtained uncertain. First in the list may be placed the oxidizing disinfectants—chlorine, iodine, bromine, etc.; and second, the deoxidizing, as sulphurous acid. The proportion of the gas to air required to destroy the vitality of disease germs cannot be stated with precision. This much is certain, however—the proportion effective is irrespirable. Articles of clothing and bedding to be acted on by these gases should therefore be hung up in a close apartment, as much gas should be disengaged as can be contained in that space, and the action should be kept up for many hours. Chlorinated lime is a convenient substance for furnishing chlorine gas in small quantity, but when a large amount is required, it can be best obtained from a mixture of common salt (18 parts), and black oxide of manganese (15 parts), acted on by sulphuric acid (45 parts), diluted by water (21 parts). Chlorine gas is unsuited to the sick room. When an aerial disinfectant is required in the apartment of a cholera patient, iodine serves a useful purpose. Some crystals, or the tincture, placed in a saucer on the mantel, gives off the vapor freely at the ordinary temperature, and much more freely if warmed. As the action of these oxidizing agents is supposed to be due to the ozone liberated by the decomposition of watery vapor, it may be better to produce this agent directly. This is readily accomplished by the oxidation of phosphorus—by placing in a vessel containing some water, a freshly-scraped stick of phosphorus: water is decomposed and a part of the oxygen passes into the state of ozone. An elegant mode of procuring the disinfecting quality of ozone in the sick chamber, is by pulverizing ozonic ether—a solution of peroxide of hydrogen in ether. Placed in the bottle of the hand-ball atomizer, or in the ordinary perfume atomizer, the ozonic ether can be effectively sprayed in the air of the apartment. This has been shown to possess a high degree of disinfectant property; but it is also very inflammable, and cannot be used in a room having an open light or fire.

The deoxidizing disinfectant of most power is *sulphurous acid.* The simple combustion of sulphur in the open air produces this gas. Notwithstanding its suffocating effects, any respirable quantity does not appear to have toxic effects. It is, at the same time, the least expensive and the most active of the aerial disinfectants. A solution of the acid, sufficiently concentrated, can be used against the solid excreta. Contaminated clothing and bedding before washing can be effectively disinfected by the gas by generating it freely in a tight apartment, and continuing the action for many hours. The rooms, halls, and passages of a house containing cholera cases should be fumigated twice a day with the gas. As has been stated, this agent does not affect the health injuriously when breathed in a quantity less than the irrespirable, although, irritation of the larynx, coughing, oppression of breathing, and a strong metallic taste are caused by it. Chlorine is far more dangerous, for there is reason to believe pneumonia may be excited by a quantity which does not cause much distress. The bleaching effects of sulphurous acid are due to the formation of colorless sulphites, which being soluble are washed out. Certain fabrics may be much damaged by it, therefore. But we cannot too strongly emphasize the fact, that no kind or degree of aerial disinfection will take the place of such care in the reception and disposition of cholera excreta, as will prevent the diffusion of dried cholera matter in the air.

More frequently, contamination of the water-supply is the source of infection. Fortunately, we have a ready means of destroying the cholera germs in water. These germs are probably destroyed at the temperature of boiling water. During the existence of an epidemic—for some time, indeed, before its actual advent—only water that has been boiled should be drunk. As, however, boiling water is insipid, because of the loss of its gases, it should be aerated by passing though one of the now much-used domestic filters, or by pouring from one vessel to another through the air. In this way, all its natural liveliness will be restored.

It should be clearly understood that contaminated water is not rendered innocuous by boiling. Some germs, there is reason to believe, resist successfully a heat of 212° F., and organic matter is not destroyed at this temperature. Not all the constituents of sewage can, therefore, be rendered harmless by boiling the drinking water containing it. This fact, then, must give additional force to our suggestions regarding the anxious care which should be given to the reception and final disposition of cholera excreta.

Whilst we thus fix our attention on Egypt and watch with anxious solicitude the progress of the cholera epidemic, we should not be unmindful of an evil always present with us. It is hardly doubtful that typhoid, like cholera, is propagated by a peculiar germ. Notwithstanding the wide differences between cholera and typhoid as regards their natural history and development, there is a certain similarity in the behavior of their causal germs. Of the two, the typhoid should be more feared, and should be the object of more careful preventive measures. The typhoid germ is always in action, and, when the aggregate mischief is summed up, it is found to be, if not more, scarcely less destructive.

The typhoid, like the cholera germ, is probably contained in the dejections of the patient. It may enter the water-supply, or, dried and pulverized, be distributed by the air, or be carried up with the gases of putrefaction from cesspools and sewers. It lies dormant for an unknown period, and acquires activity under conditions not now ascertainable. Entering the human body like the cholera germ, it finds its favoring habitat in the intestinal canal, but differs from the latter in exciting a slowly developing disorder.

It is obvious, then, that the disinfectant treatment of cholera poison is equally applicable to the typhoid. If we substitute for "cholera disinfection," *typhoid disinfection*, our remarks may still be made. In closing, we can render no better service than to urge on our readers the necessity of a careful and complete disinfection of typhoid dejections, if we would rid the community of a perennial pest.

REVIEWS.

A Practical Treatise on Impotence, Sterility, and Allied Disorders of the Male Sexual Organs. By S. W. Gross, A.M., M.D., etc. Second edition, thoroughly revised. Large 8vo. pp. 176. With sixteen illustrations. Philadelphia: Henry C. Lea's Son & Co., 1883.

The author of this monograph is a man of positive convictions and vigorous style. He utters no uncertain sound when he speaks, and states his opinions, as he feels them, strongly. This is justified, in the case of his publications thus far issued, by his experience, which has been considerable, and by his study, which has gone hand in hand with his experience. In regard to the various organic and functional disorders of the male generative apparatus he has had exceptional opportunities for observation, and his book shows that he has not neglected to compare his own views with those of other authors. The result is a work which can safely be recommended to both physicians and surgeons as a guide in the treatment of the disturbances it refers to. It is the best treatise on the subject with which we are acquainted.

Transactions of the College of Physicians of Philadelphia. Third Series. Volume the Sixth. 8vo. pp. xliv. 451. Philadelphia: Printed for the College, 1883.

The present volume of *Transactions* is by far the largest and most valuable that has ever been issued by the College, and reflects the increased interest in its welfare taken by the Fellows.

The volume contains thirty-one papers, full abstracts of which have, from time to time, appeared in our reports of the meetings of the College. Two of the most notable papers were read by special invitation of the College. That on the *Bacillus Tuberculosis* will be remembered as a lucid and most interesting exposition and demonstration made by Dr. Whittaker, of Cincinnati, just after his return from study in Koch's laboratory, and Prof. Leeds' able contribution to our knowledge of the value of the various *Infant Foods* now on the market is still fresh in the minds of our readers.

The volume is handsomely printed and bound, and has been carefully edited by the Recorder of the College, Dr. J. Ewing Mears.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, May 7, 1883.

The President, S. D. Gross, M.D., LL.D., D.C.L., in the Chair.

Dr. John H. Packard reported the following case of

SUPRA-HEPATIC ABSCESS.

B. Bradley, æt. 33, an Irishman, of good constitution and sober habits, had been under the care of Dr. T. Stanton Crowley for several weeks, his first symptoms having been severe chill and excessive abdominal pain. Subsequently he had much pain, flatulence, and constipation. He was several times threatened with general peritonitis, but the symptoms were controlled by turpentine stupes, etc.

Dr. Crowley asked me to see Bradley, on March 31, on account of a firm, tense swelling in the right hypochondrium, attended with some hectic and a good deal of embarrassment of respiration.

On the 19th of April, I saw the case again. There was now decided fluctuation, but percussion was abnormally clear all over the right chest and down over the tumor, and there was metallic tinkling on auscultation. We decided upon aspiration.

April 20, Dr. W. Pepper examined Bradley, and agreed with us as to the propriety of aspiration, which I proceeded at once to perform, but could only obtain a quantity of very fetid gas. At the time, we were under the impression that the instrument had entered a distended colon. The operation gave a considerable amount of relief to the breathing, but the man continued to sink, and died about thirty hours afterward.

An *autopsy* was made on the 23d by Dr. Crowley and myself. The body was well developed and muscular; it had been kept on ice, and the degree of rigor mortis could hardly be determined. There was no decomposition. On cutting into the abdomen, a cavity was opened, which proved to be an enormous supra-hepatic abscess, the walls lined by a thick deposit of cheesy lymph. From this cavity there was sponged out about a gallon of fetid pus; it contained also, as nearly as we could judge, a like bulk of offensive gas. The diaphragm was pushed very much upward, compressing the right lung into an extremely small space. Within the very much reduced pleural cavity there was thick, creamy pus, while the base and inner and posterior surfaces of the lung were firmly adherent by lymph. The pericardium and left pleura were full throughout of inflammatory adhesions, and the pericardium covering the heart was much thickened by lymph effused in the subserous areolar tissue. Traces of general peritonitis were observed. The liver was mottled, and stained of a dark olive-green to the depth of about a quarter of an inch all over its upper surface. It was clear that the aspirator needle had been inserted into the cavity of the abscess, but that the surface of the liquid was beyond its reach, so that a portion of the gaseous contents only could be withdrawn in this way.

Dr. J. Ewing Mears thought that we could readily see why, from the position of the abscess, the patient being on the back, that there should be resonant percussion on the anterior surface of the chest, and that the resonance would be tympanitic. As depicted on the board, it represents a case of hydro-pneumothorax—air and liquid in the chest.

DR. PACKARD replied that it was tympanitic. It was abnormally resonant. Dr. Pepper was inclined to think that it was a case of hydro pneumothorax.

THE PRESIDENT asked how far the fluid was from the external surface?

DR. PACKARD said it was so far that when the aspirator needle was introduced as far as it would go, it did not reach the fluid. Dr. Pepper suggested that if the man lived, the aspirator needle should be introduced in the ordinary place for aspirating the pleural cavity. In which case, we should have drawn off some liquid, but would have given the patient no relief.

DR. CHARLES B. NANCREDE said that in connection with this case he would like to mention another of peri-hepatic abscess. In many respects it was like the one described, but there was no collection of gas in the pleural cavity. The history of the case is as follows: A young man, aged about 19, was admitted to the medical ward of the Episcopal Hospital under the care of Dr. Morris Lewis. There was absolutely no history of any kind to be elicited. He stated that he only began to complain ten days before admission; previous to that time he was well. He then became sick in a vague sort of a way, with malaise and the like; of course, if he had been under careful observation at this time, hectic would have been detected. On admission, the thermometer and pulse-rate gave evidence of suppuration in some part. The physical examination showed that the liver was apparently pushed up about two ribs above the normal; dulness extended downward to about two inches above the umbilicus. In the back, fluctuation could be detected. Introducing an aspirating-needle at this situation, Dr. Lewis drew off half a drachm of very offensive fluid. His opinion was that it was an abscess of the liver. I came to the conclusion that it was peri-hepatic, and that one wall was formed by the colon, and that this accounted for the intensely fetid gas. I tapped him, and obtained pus on two or three subsequent occasions. He got very much better, but one night was found dead in bed. The post-mortem was made by myself several hours after death. Some frothy pus was found in the trachea, but although perforation of the stomach was found, there was no pus in the stomach. The cavity of the abscess could not have contained more than half a pint of fluid. The opening was three or four inches from any part of the abscess cavity. At the post-mortem there certainly was no portion of the gut or hollow viscera within several inches of the abscess cavity. The lungs were carefully removed and water forced into them, but no perforation was found. There was no pus in the stomach, nor any discharged by the bowel. How the pus got into the trachea and what was the cause of death, I do not know. What I should like to know is, where the fetid pus comes from when the gut has no connection with the abscess.

DR. JOHN H. PACKARD suggested that there had been an escape of pus, which had been vomited, and that a portion had been drawn into the trachea.

DR. NANCREDE replied that the opening in the stomach was three or four inches from the abscess.

DR. FERDINAND H. GROSS exhibited a

SPINDLE-CELLED SARCOMA.

The specimen of periosteal spindle-celled sarcoma which I have to exhibit, was removed by amputation of the right arm at the junction of its middle and upper thirds. The patient, Conrad Seybert, a German, aged sixty-two years, and by occupation a carpenter, presented himself at the out-patient department of the German Hospital, for the first time on April 23d (two weeks ago), and was admitted to the Hospital on the following day. My resident, Dr. A. B. Hirsh, who saw the patient when he applied to the dispensary, informs me that the man was in great pain, presented an anæmic appearance, and that his arm hung helpless by his side. On examination in the hospital, I found a tumor of the size of a large fist occupying mainly the posterior aspect of the lower end of the right humerus, extending over both condyles, but bulging out considerably on the inner side. It was slightly lobulated, and the greater part of the mass imparted a rather firm, somewhat elastic feel, while at several points it was quite soft, and at one of these the resident had made a puncture, believing there was contained here a collection of pus, which, however, proved not to be the case, a very little bloody fluid only escaping. The movements of the elbow-joint were much impeded by the proximity of the growth, but the structures of the joint itself did not appear to be involved in the disease, nor did this extend to the ulna or radius. The forearm and hand were swollen, the subcutaneous veins were not markedly distended; one of the lymphatic glands in the axilla, however, was slightly enlarged.

In making inquiry as to the early history of the case, the patient stated with positiveness that the tumor began to grow about ten months previously, having been preceded for several weeks by violent shooting pains that extended down the arm to the fingers. He had not for many years sustained any injury to the arm, but he stated that twice during his life he had hurt himself at the spot where the tumor afterwards made its appearance. Although these injuries occurred many years ago, the first one in his childhood, by a fall from a tree, I mention it here because the patient dwells upon the fact with some emphasis that ever afterwards this spot upon the inner condyle remained morbidly sensitive, and on being struck would usually continue to pain him for ten or fifteen minutes. When about twenty-eight years of age, while engaged at work as a carpenter, he fell from a building and again injured his arm at the same place, and was disabled from pursuing his usual occupation for three or four months. The occasional tenderness when the part was struck since continued. The patient is positive that on neither of the occasions stated did he sustain either a fracture or dislocation, and he is equally certain that no traumatism has since occurred. When he first noticed the new growth it was hard, immovable, and about the size of a marble. There appears to have been no complete intermission in its growth, though for a time its increase was rather slow, but later on it grew with constantly increasing rapidity. I pronounced the tumor to be a sarcoma, and advised amputation. On the 27th of April (ten days ago), after consultation with my colleagues at the hospital, the patient was etherized, and I performed the operation at the point above indicated.

The specimen as here presented has been bisected down to the bone, to which it is loosely attached. In the line of this incision the bone is denuded of periosteum, but shows no other signs of disease. The mass is soft, and I do not discover in it or its capsule any hard or long points. In dividing the tumor, a small area of interstitial hemorrhage has been exposed, but no large bloodvessels appear to course through the neoplasm. My colleague, Dr. Barton, took several pieces of the growth for microscopic examination, and informs me that it is a spindle celled sarcoma with some round cells intermixed.

Since the amputation the patient has had no bad symptoms. The traumatic fever did not reach a high grade, and the wound looks very well. He has no pain to speak of, and sleeps without the use of narcotics, while before the operation he required these constantly. The enlargement of the lymphatic gland in the axilla has entirely disappeared, and seems to have been simply hyperplastic, due to irritation, and probably contained no sarcomatous elements.

Dr. O. H. Allis said he had an opportunity of examining this case before he went to the German Hospital. He called at Jefferson College Hospital on two occasions, and we advised him to return and have the arm amputated, but he did not profit by the advice. I thought, and I presume that Dr. Gross also thought, that the tumor was attached so tightly to the bone that it might prove to be an osseous tumor. There were hard points on the tumor. In some places it was soft and nodulated, the softened parts being the size of an ordinary hen's egg. I was surprised to find that the bone was not involved, and that it could safely be removed at the point at which it was amputated.

Dr. Packard asked whether it would not have been safer if the arm had been removed at the shoulder-joint. Where the bone itself is involved, the removal of the bone at the articulation makes a great difference as to the probability of the return of the disease. Whether this rule holds good in regard to periosteal tumors, he could not say. It seemed to him that greater safety would have been insured by removal of the bone at the shoulder-joint.

Dr. F. H. Gross, in reply, said: My colleague, Dr. Barton, had the same idea that the tumor started from the bone, but I believed it to be periosteal. I thought that I could discover movement, and therefore preferred the operation which I performed to amputation at the shoulder-joint. There are others who, perhaps, can state whether an osseous tumor is more likely to return than a periosteal tumor.

Dr. Barton said that after the man was under ether, it was readily determined that the tumor was separate from the bone.

Dr. J. Ewing Mears said it is well known that the tendency to recurrence in spindle-cell sarcoma is not as great as in round-cell sarcoma. This mass was, he believed, a spindle-cell sarcoma. This, of course, could not be determined previous to the microscopical examination. In these cases of sarcoma, no matter in what part of the osseous system they may appear, it is, I believe, an accepted fact that they are not liable to return after complete extirpation.

The President.—The cause that produced the disease originally in the man may be able to cause the development of another tumor, but in the true sense of the term, this cannot be spoken of as a return.

Dr. S. W. Gross.—There are one or two points on which I may be able to throw some light. In the first place, let me say that the small spindle-cell is equally malignant with the small round-cell sarcoma. A small cell tumor, no matter what the morphology of the cell, constitutes a medullary tumor. The large spindle-cell sarcoma is comparatively innocuous.

In regard to the question whether or not it would have been better to remove the bone at the shoulder-joint, that could have been determined at the time of operation by making a section of the bone. The medulla is likely to become affected through the Haversian system. If the medullary tissue were affected, the amputation would have to be made at a higher point. In the case that has been described, I should have amputated at the shoulder-joint. Small-cell periosteal sarcomata are among the most malignant of all tumors. The chances are two to one that this man will die from secondary growths in some part of his body, as, for instance, in the lungs.

Dr. F. H. Gross.—I would ask whether these tumors are more common in the young, or in the old?

Dr S. W. Gross —Spindle-cell sarcomata are tumors of late life.

Dr. Mears.—I can only speak of some experience with periosteal tumors in connection with the jaws. I have removed a number of spindle cell sarcomata from both the upper and the lower jaws. Patients living in this city, from whom I removed such tumors six, eight, ten years ago, are still living and in good health. While the number is not large, yet I am inclined to think that in these cases the return of the disease is not to be expected. The specimens from these patients were examined by competent microscopists, who pronounced them to be small spindle cell sarcomata. The investigations of Dr. Gross in regard to this subject have been such as enable him to speak with authority, and I would ask him if it was not the opinion, a few years ago, that spindle-cell sarcomata were on the border-line, and were not as malignant as the round-cell variety?

Dr. S. W. Gross.—A few years ago we did not have as accurate a knowledge of histology, and we did not make the distinctions which we do now; but there is no doubt about the fact that the small spindle-cell sarcoma is excessively malignant as contra-distinguished from the large-cell tumor. I was speaking of sarcoma of the humerus and of the long bones, not of the jaws. The situation of the tumor greatly modifies its malignancy. Sarcoma of the jaw is far less malignant than sarcoma of the long bones.

Dr. C. Nancrede.—There is an anatomical fact which may explain why sarcoma of the jaws—especially of the upper one—should be less malignant than the same disease in the long bones. The disease tends to disseminate itself through the vascular system, and not through lymphatics. There is practically no medullary tissue worth mentioning in the upper jaw; there is very little intra-osseous vascular tissue whereby the general system can become involved.

Dr. J. Packard.—I do not want to prolong the discussion, but I should like to say that of all tumors we operate on, it seems to me that there can be none more hopeless than tumors of the upper jaw. I would ask if the members of the Academy have not had a similar experience? When we deal with polypus of the antrum, or polypi of the nose, which appear to be perfectly simple, we always have before us the grizzly shadow of what may be a malignant tumor of the upper jaw. Perhaps, after one or two operations, the disease returns and goes on to the death of the patient. It seems to me that the upper jaw must be made an exception; it may be that in the lower jaw sarcomata are not so dangerous. I can look back on very few cases in which the disease did not return. I know of one or two cases in which you, Mr. President, operated, and in which the disease returned and the patient succumbed.

The President.—I hardly remember one in which it did not return.

Dr. S. W. Gross.—Do you mean sarcoma as defined by the minute anatomy of the cell, or do you mean carcinoma? Carcinoma will return; are you speaking of sarcoma proper?

Dr. Packard.—My impression is that the tumors were sarcomata. I used to belong to the Pathological Society, and was its president for a couple of years; but, if I should now go to a meeting of the Society, I should keep very quiet. I know nothing of the refinements of pathology of the present day. I had always believed that malignant tumors of the upper jaw were sarcomata. It certainly seems to me that we may have here a distinction without a difference.

Dr. S. W. Gross.—There is an exceedingly great difference. The difference in situation makes a great difference as to the malignancy of sarcoma. Sarcoma of the breast is far more malignant than carcinoma of that part. I do not believe that medullary sarcoma of the breast is ever cured. Carcinoma appears in the young, sarcoma in the old.

Dr. Mears.—The position of a tumor—whether it arises from the periosteum or whether it arises from the antrum—makes a great difference as to its malignancy. Periosteal tumors arising from the fibrous periosteum can be removed without much probability of their returning; but when you have a tumor which takes its origin from the bone, you have a very difficult tumor to deal with.

In regard to the return of sarcoma, Dr. Gross has said that sarcoma is more malignant than a carcinoma. I saw a case in which a distinguished surgeon had removed a tumor of the breast which he regarded as cancerous. He asked me to attend an operation for the removal of a tumor from the vertex of the skull in the same patient. He showed me the breast, and said "there is a case of cancer cured." The cicatrix was soft and free from disease. I pointed to the large osseous sarcoma of the head, and said "there is your cancer of the breast." In other words, there was a return of the sarcoma. Microscopical examination showed that it was a sarcoma. The interval between the two operations was one year.

The President. — There is a great difference in regard to the return of the disease in other parts of the body after its removal from one locality.

Dr. Addinell Hewson.—Dr. Richard Norris, in a recent work on the pathology of the blood, calls attention to the growth of lymph-cells from the medullary canal of the bones. This may explain the very frequent origin of these tumors in the long bones. He gives my grandfather the credit of having described both the large and the small cells; he makes a difference in the value of the two in the fact that the small cells are the source of the blood-corpuscles and of all morbid growths.

Dr. Barton.—There has been another reason suggested why malignant tumors of the upper jaw are so liable to return: it is owing to the fact that it is necessary that these tumors should be developed to a considerable extent before a diagnosis that would warrant so serious an operation as the removal of the upper jaw can be made. The jaw is usually immensely disfigured, the tissues so thin that an exploring needle could be thrust into the antrum, and, perhaps, with openings and ulceration over the surface, or through the palatine process, into the mouth. Earlier than this the diagnosis cannot be made with such certainty as to warrant the removal of the jaw.

Dr. Packard reported that the patient operated on for

STRANGULATED VENTRAL HERNIA,

whose case was related at the last meeting (see The Medical News for July 14, 1883, p. 45), had continued to improve steadily. The wound had entirely healed, and the parts were quite free from pain or soreness. The silver-wire suture was buried in the tissues, but gave no sign of its presence.

Some delay had been caused in her return to active life by the formation of a superficial abscess in the supra-pubic region, but this has now opened spontaneously, and is healing up. Her bowels are regularly moved every day, and her general condition is excellent.

NEWS ITEMS.

MONTREAL.

(From our Special Correspondent.)

Endowment of McGill Medical Faculty.—At the semi-centennial celebration in October last, a gentleman offered the Faculty $50,000, if, by the first of August, 1883, an equivalent sum was raised in commemoration of the late Dean, Dr. G. W. Campbell. This has been done, and on the 19th inst. Hon. Donald A. Smith handed Dr. Howard a check for the $50,000, to be known as the "Leanchoil" endowment.

Mr. George Stephen has given $50,000 to the general hospital for a memorial wing to the late Dr. Campbell, who was for many years a surgeon to the Institution and Chairman of the Medical Board.

The Laval Question.—The battle between the two French Schools of Medicine in Montreal still rages fiercely, and the old *École de Médicine et de Chirurgie* is making a gallant fight for existence, though against terrible odds. The end is now not far distant. It will be remembered that when Laval University of Quebec, established a branch at Montreal in 1876, the existing French School was taken as its medical faculty. Troubles arose and the school severed its connection with Laval, preferring to be independent. Some of the professors, however, elected to remain with Laval and formed another faculty, and the struggle has been between these two bodies. The decrees from Rome state that there shall be but one Catholic school, and that Laval must be supported. The old school has had a good deal of encouragement from the clergy of the Montreal diocese, and moreover, it has had for years agreements with the Sisters of the Hotel Dieu, the Maternity Hospital, and the Dispensaries, whereby it controls the medical teaching, etc., in these institutions. Extreme measures have finally been taken by the Bishops, who have commanded the ladies of these establishments to close their doors to the professors and students of the old school, and admit only those of Laval. To this the sisters have consented, although in so doing they are probably liable to a civil action.

A pastoral letter from the Bishop of Montreal was read in all the churches a Sunday or two ago, condemning the old school as in rebellion against the church, and virtually excommunicating the professors and students. Dr. Desjardin one of the professors, has gone to Rome to make a final appeal to the Pope, and if unsuccessful, the school must doubtless close. The students remain loyal, and it is announced that the session will open as usual on October 1st. A legal action may compel the Sisters of the Hotel Dieu and Maternity Hospital to abide by their agreements, but if this is not done, the days of the old Montreal School of Medicine are numbered.

Canada Medical Association.—The Annual Meeting takes place at Kingston, Ont., on the 5th, 6th, and 7th of September, under the Presidency of Dr. John Mullin, of Hamilton.

Cholera Mortality in Egypt.—

	Cairo.	Alexandria.	Total for Egypt.
August 21,	1	37	131
" 22,	. . .	31	. . .
" 23,	0	33	. . .
" 24,	. . .	26	200
" 25,	. . .	22	167
" 26,	. . .	17	81
" 27,	. . .	12	171

The disease is said to have appeared in Sumatara, but the report lacks confirmation.

The Yellow Fever at Pensacola.—Two new cases of yellow fever have been reported at the Navy Yard. Surgeon Owen died on August 22, and his wife on the 27th, and on the same day their second daughter was stricken down with the disease.

Passed Assistant Surgeon Guiteras has volunteered for duty at the Yard, and has already arrived there.

The house to house inspection at Pensacola, ordered by Surgeon-General Hamilton, resulted in the discovering of two cases of supposed yellow fever in a sailor's boarding-house on Palafox Street wharf, which were removed to the Quarantine Hospital on Santa Rosa Island, where one of the cases died on the same evening. On post-mortem examination, the disease proved not to be yellow fever. The house and contents were destroyed, and the premises were surrounded by a guard. The men proved to be deserters from the bark Dogmar from Limerick, which arrived at Pensacola on the 17th, after three weeks spent up the Bay. The Dogmar brought a clean bill of health. Surgeon Murray, under date of August 23, reports these cases as malarial rheumatism.

A cordon has been established around the city, which is seven miles from the Navy Yard.

Origin of the Cholera at Damietta.—A very interesting report has been published by Chaffey Bey as to the origin of the outbreak at Damietta. After a careful analysis of all the circumstances of the case, he arrives at the conclusion that the cholera was not imported, but broke out spontaneously on account of the condition of the river and city, which this year presented conditions similar to those found on the banks of the Ganges when the epidemic made its appearance. The great fair at Damietta attracted a crowd of 15,000 people, who for eight days lived on foul water and decayed fish.

The German Cholera Commission.—The commission, of which Dr. R. Koch is President, nominated by the German Government to study the nature of the cholera outbreak in Egypt, sailed for Alexandria on the 16th of August.

Cholera Precautions in Paris.—In his report to the Conseil d'Hygiene, Dr. Dujardin-Beaumetz recommends, as preventive measures in case of an outbreak of cholera, that solutions of sulphate of copper and zinc, and especially chloride of zinc, be used for the disinfection of clothing and bed-linen. During the course of the disease the patient should be isolated; curtains, carpets, and hangings should be removed, and thoroughly disinfected with a solution of these salts (℥viss–Oj). After the room has been emptied, a fire should be built, and the room thoroughly disinfected—burning charcoal containing ℥v of sulphur for each cubic yard of the room. The room should be tightly closed for twenty-four hours, after which it must be ventilated for one week before use.—*L'Union Méd.*, August 9, 1883.

Personal Precautions against Cholera.—M. Pasteur, according to *Le Temps*, has formulated the following instructions for the personal protection of the members of the French Commission which has gone to Egypt to study the cholera outbreak.

These instructions are instituted on the hypothesis, which he considers very probable, if not certain, that cholera does not enter the human organism by the air-passages, but that it does so only by the digestive canal, unless under very exceptional circumstances: 1. Not to make use of the drinking water of the locality in which the mission will be located without having previously boiled the water, and shaken it well, after it has become cold, for two or three minutes, in a bottle half filled; or the water may be put into vessels previously heated, "vases flambés,"—that is to say, vessels that had been subjected to air heated to about 300° Fah. or even more, the higher the temperature the better. The natural mineral waters may be employed with advantage instead. 2. Make use of wine that has been heated in bottles to about 135° Fah., and which should be drunk in glasses also previously heated. 3. To make use of alimentary substances only after being well cooked, and fruits in their natural state, but previously washed with water that had been boiled, and preserved in the same vessels in which it was boiled, or had been transferred into those previously heated. 4. To make use of bread cut up into thin slices and submitted to a temperature of about 300° Fah., during twenty minutes or more. 5. All the vessels employed for alimentary purposes should also be previously subjected to a temperature of 300° Fah. or more. The bed-linen and towels should be plunged into boiling water, and then dried. 7. The water for washing or bathing should be previously boiled, and, after being cooled, mixed with solutions of thymic or of carbolic acid, the former in the proportion of 1 to 500 parts, and the latter 1 to 50 parts. 8. The hands and face should be washed frequently during the day with boiled water, and to which should be added solutions of thymic and carbolic acid. 9. It is only in cases where the bodies of patients who have died from cholera or their soiled linen has to be handled that it would be necessary to cover the mouth and nostrils with a small mask formed of two pieces of thin plates of metal, enclosing between them a little cotton-wool of not more than one centimetre thickness, the mask having been submitted to 300° Fah. only, and renewing the temperature of 300° on each fresh exposure to contagion.—*Gaz. Hebdom.*, August 10, 1883.

State Medical Society of Wisconsin.—The State Medical Society of Wisconsin will hold an adjourned session at the Court House in the city of Milwaukee, commencing on Tuesday, September 4, 1883, at eight o'clock P.M. This meeting is to take the place of the regular annual session, which, without the transaction of any general business, and at the request of several members, was adjourned to the above-named date.

As the President, Dr. T. P. Russell, is now absent in Europe, there will be no Presidential address.

It is expected that an unusual amount of time will be devoted to the discussion of medical topics, and by vote of the last session of the Society, the subject of the paper then presented by Dr. Senn, to wit—"the Pathology and Morbid Anatomy of Tubercle"—was made a special order for discussion at this meeting.

Another subject of special interest, and one which, it is anticipated, will be the subject of profitable discussion, is presented in the resolution by which the Committee on Pathology was instructed to inquire into "the possibility of relationship and causation of erysipelas, diphtheria, and puerperal fever."

The Chicago and Northwestern, the Milwaukee and St. Paul, the Wisconsin Central, the Milwaukee and Northern, and the Milwaukee, Lake Shore and Western Railroads will return members who have paid full fare over their own roads, in going to Milwaukee, for one-fifth of the usual rate, on presentation of certificate of attendance, which will be furnished by the Secretary.

The Lehigh Valley Medical Association.—The third annual meeting of this Society was held at Easton on August 15th. The President, Dr. Traill Green, delivered an address on "The Doctor of the Olden Time," and Dr. C. K. Mills, of Philadelphia, by invitation, read an interesting paper on hysteria.

Dr. R. Leonard, of Carbon, was elected President for the ensuing year.

Smallpox in New Orleans.—There were nineteen deaths in New Orleans from smallpox for the week ending August 18th.

Havard Medical School.—It is announced that Dr. Calvin Ellis has resigned the Deanship of the Harvard Medical School, and that Dr. H. P. Bowditch has been elected his successor.

Sir William MacCormac sailed from Liverpool on the 23d ult. on a brief visit to this country.

The Garfield Memorial Hospital.—A statement has recently been published to the effect that the plan of establishing a Garfield Memorial Hospital in Washington City had been abandoned for lack of support and that the money thus far contributed for that purpose will be turned over to the Garfield Monument Fund. Mr. Thomas Fisher, of the Garfield Hospital Board, states that the report of the abandonment of the hospital scheme was entirely without foundation.

On the contrary, the Board has purchased the L. H. Schneider property, at the head of Tenth Street, on the elevation overlooking the city, for $38,000, and obtained possession of it on August 1st. There is a fine double brick house on the place, with out buildings and nearly seven acres of ground. It is the intention of the Board to begin the erection of a wing to the house, to cost $15,000, and Dr. J. S. Billings will superintend the work. The hospital will be open for the reception of patients soon. The Board has the money in bank to pay for these improvements, and is in earnest about this matter.

The Date of Expiration of the Term of Service of the Surgeon-General of the Navy in Dispute.—A Washington telegram to the *Tribune* states that in 1879 there was a vacancy in the office of Surgeon-General and Chief of the Bureau of Medicine and Surgery in the Navy, which was filled by the selection of Medical Inspector Philip S. Wales, who was appointed Surgeon-General on August 1, 1879. The appointment was bitterly opposed by several surgeons who were Dr. Wales' senior in rank, and they waged war against his confirmation by the Senate. They were defeated, and on January 20, 1880, Dr. Wales received his commission for four years. The present aspirants for the place, who comprise all the medical officers of the Navy senior to Dr. Wales, contend that his term expired on August 1, four years from the date of his original appointment, and that all official acts performed by him since that date are illegal. Surgeon-General Wales insists that, unless sooner removed by the President, his term of office will not expire until January 20, 1884, four years from the date of his commission. He is a candidate for reappointment.

There is some talk of an effort to have the question as to when Dr. Wales' term expires referred to the Attorney-General for his opinion, inasmuch as this is the first controversy of the sort that has ever arisen in the naval service.

The Composition of Hostetter's Bitters.—Internal Revenue Commissioner Evans has sent a circular to all collectors and revenue agents, inclosing a copy of his letter to Hostetter & Smith, respecting the "bitters" made and sold by them. In part the circular reads as follows: "The analysis of the compound shows it to be made of a very strong alcoholic liquor, and very little else—so little of anything else that information received at this office leads to the belief that it is now being sold very extensively as an alcoholic beverage, and that efforts are being made to evade the law requiring payment of the tax due the United States from retail liquor dealers. These facts, and especially the analysis of the bitters, which itself justifies very great suspicion, lead me to enjoin the utmost vigilance upon all revenue officers, so that no one liable for the tax shall escape its payment by any evasion or false pretence whatever. It may also be added that the terms of the letter to Messrs. Hostetter & Smith are applicable to the case of every other preparation of a like alcoholic character, and especially where there are grounds for strong suspicion that distilled spirits are sold under the guise of a medicine.

Health in Michigan.—Reports to the State Board of Health for the week ending August 18, 1883, indicate that tonsillitis, cholera infantum, and bronchitis have increased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending August 18, and since, at eighteen places, scarlet fever at twelve places, and measles at nine places.

Hay fever is now quite prevalent, ragweed beginning to blossom August 17.

The correspondent at Hudson reports an unusual tendency, for that locality, to congestion and irritation of nerve-centres and the meninges of the spinal cord and brain.

Obituary Record.—Died in Paris, on August 5th, Prof. Parrot, at the age of 59 years. Receiving his degree of Doctor in Medicine in 1857, he rapidly rose to Agrégé de Faculté in 1860, Physician to the hospitals in 1862, Professor of the Faculty in 1876, Member of the Academy in 1878, and Physician in Chief of the Legion of Honor in 1879.

—— Our Italian exchanges record the death, in Florence, of Dr. Filippo Pacini, Professor of Topograghical and Microscopical Anatomy, at the age of 61 years. He was the discoverer of the corpuscles which bear his name.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 20 TO AUGUST 27, 1883.

Clements, Bennett A., *Major and Surgeon.*—Relieved from duty with the Army Medical Examining Board, New York City, N. Y.—*Par. 11, S. O. 193, A. G. O., August* 22, 1883.

Middleton, J. V. D., *Major and Surgeon.*—Relieved from duty at Fort Hays. Kansas, and assigned to duty at Fort Leavenworth, Kansas.—*Par. 2, S. O. 169, Department of the Missouri, August* 18, 1883.

Williams, John W., *Major and Surgeon.*—Granted leave of absence for one month on Surgeon's certificate of disability.—*Par. 1, S. O. 109, Department of the Columbia, August* 8, 1883.

Bartholf, John H., *Captain and Assistant Surgeon.*—Assigned to temporary duty at Vancouver Barracks, W. T.—*Par. 2, S. O. 109, Department of the Columbia, August* 8, 1883.

Finley, J. A., *Captain and Assistant Surgeon.*—Relieved from duty at Fort Concho, Texas, and assigned to duty at Fort Stockton, Texas, as Post Surgeon.—*Par. 1, S. O. 101, Department of Texas, August* 16, 1883.

Kimball, James P., *Captain and Assistant Surgeon.*—Relieved from duty in Department of the Platte, and to proceed to New York City, and report in person to the President of the Army Medical Examining Board, for duty as a member of that Board, *vice* Surgeon Clements, relieved.—*Par. 11, S. O. 193, A. G. O., August* 22, 1883.

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

SOME DISEASES OF THE FEMALE ORGANS OF GENERATION, CHARACTERIZED BY NEW GROWTHS.

A Clinical Lecture, delivered at the Long Island College Hospital, Brooklyn, N. Y.

BY ALEXANDER J. C. SKENE, M.D.,

SURGEON TO THE HOSPITAL, AND PROFESSOR OF GYNÆCOLOGY IN THE LONG ISLAND COLLEGE HOSPITAL, BROOKLYN, N. Y.

(Reported by EDWARD DEVELIN, M.D.)

GENTLEMEN: To-day I call your attention more especially to *disease* of the female organs of generation, characterized by those neoplasms which often result so seriously to the patient, frequently terminating in death, but more generally in chronic disease and inability to continue their normal functions. I desire to call your attention to these diseases and conditions, that you may the more readily recognize them in the incipient stage, and apply such means for their relief as may result most satisfactorily both to the patient and to you as medical men.

OVARIAN TUMOR.

This woman came to me ten months ago; she then presented the same outlines as she does now, but with this difference, that at that time her general appearance was much better than it is now. She was then in good flesh, with rosy cheeks, and was not emaciated as she now is. You observe here the enormous distention of the abdomen; but, apart from this, at that time she had all the appearances of being a strong, vigorous woman.

At that time we made a diagnosis, and relieved her of this enormous distention of the abdomen, removing seventeen quarts of fluid, of a chocolate consistency, from this abdominal tumor with which she is afflicted. I desire you to specially notice this patient, as she gives the physiognomy of her disease, and which is described in our books as the facial expression of ovarian disease.

After the fluid was withdrawn, she was quite comfortable, and returned to her home, until four months ago, when she again presented herself in the same condition as before. The tumor was again aspirated, and somewhere in the neighborhood of the same quantity of fluid removed as previously. She was then allowed to return home, and to-day returns with this enormously distended abdomen precisely the same as upon the two previous occasions.

This patient cannot lie down without great distress, and you observe, as she is now sitting in an ordinary chair, that the tumor is so immense that it projects beyond the knees. We will, however, place her in the recumbent position, and you now notice that there is no adipose tissue upon the abdominal walls; we also find flatness at all points of this distended abdomen; it is also irregular in its outline; I cannot flatten or displace this abdomen by pressure while she is lying here as I could if it were a free fluid, simply because it is fluid in a cyst, distended until its walls are tense. There is no difficulty here in obtaining diametric fluctuation. I tap lightly upon this left side; there is no difficulty in detecting the wave upon the opposite side; so we have it with peripheral percussion.

The point is to make out if this fluid is encysted; this we can easily accomplish. Now I get clear peripheral fluctuation all around except upon the left side, and I find at this point that it is semi-solid and irregular. On making a vaginal examination, I find also in the cul-de-sac of Douglas a solid mass which belongs to this growth within the abdominal cavity. We notice also upon the abdomen that the vessels, insisting upon their privileges, have made deep furrows in the abdominal walls, this enlargement of the veins being entirely owing to the pressure brought to bear upon them. As I pass my hand lower down, I also come to a solid mass; and here you will observe that the distance from the symphyses pubes to the umbilicus is much shorter than normal. Now the question probably which occurs to you is: If I made my diagnosis of this case a year ago, why did I not remove this tumor? That is the only proper treatment for ovarian tumor. I will state that I did not deem it expedient to remove it for what appeared to me to be good reasons, although at that time she was in much better condition than she is now. I do not understand how such patients can carry these enormous tumors with the facility that they do. Keith removed a tumor weighing one hundred and twelve pounds, when the entire weight of the woman previous to its removal was only one hundred and eighty-seven pounds, so that in his case he literally removed the woman from the tumor, as his friends laughingly remarked. In this case before you, however, it was not the size of the tumor of which I was afraid; you notice that the umbilicus is low down, and I presumed from that that the solid portion of the tumor which was in the pelvis had formed adhesions to the bladder, uterus, and abdominal walls, showing that these parts would not yield, and that those above had been overcome by these adhesions and dragged down. I obtained further evidence that there were adhesions with the bladder and uterus, because, in passing the sound into these organs, I found that they were immovable. This told me it would be extremely difficult to remove this tumor, even if it were possible. More than that, I found that this solid mass, high up on the left side, was adherent probably to the stomach and diaphragm. As I made pressure, the fluid could be displaced downwards, but at this point the solid mass was immovable.

Now if there are no adhesions in these tumors, you can slide them up or down in the abdominal cavity; but in this case I could not do so. I therefore thought it best to first aspirate, and by this means determine the relation of these adhesions. The fluid was accordingly withdrawn, and we then found a solid mass adherent to the diaphragm upon this left side, and, when the abdominal walls were relaxed, I could distinctly feel this solid mass as being part of the cyst. I thought at first that it might be an enlarged spleen which was pushed forward by the tumor, but I found it was a part of the tumor itself. This growth, then, was adherent to the diaphragm, and also to all the pelvic organs.

What the solid portion in the pelvis is I do not positively know; it may be fibrous, or composed of little cysts, and above, I presume, we have the same condition of things. It does not present the characteristics of the spleen, liver, or stomach, or anything that might be looked for in that part of the abdomen, and from this I judge it to be a mass of small cysts. Had this growth not been adherent so extensively, I could have removed it; but with these adhesions I had not the courage to operate, as I was almost sure I should fail. Not necessarily, however, for we have cases on record in which the tumor has been adherent to the liver and stomach, and yet the patients made a good recovery after the operation. There are some of Keith's cases (and if I did not know the man so well, I should almost doubt it) which have been recorded by others in which such operations have been eminently successful. But then he is the surgeon of surgeons in ovariotomy, and can do more in less time than any other man; his knowledge and power to deal with these cases are wonderful. He might perhaps have operated in this case, but I would prefer not to. I told the patient how she was situated, and she thought if I could relieve her for a few months more, to look after her family, she would prefer to do so than run the risk of an operation; she was therefore aspirated as desired.

But even in mild cases this tapping involves danger, so that I am sometimes unwilling to do it, as patients have died from it. They do not die so often now, because the aspirator can be used with less danger than the original method of tapping, the fluid being less liable to escape into the cavity of the peritoneum as the operation is now performed. I believe in this case the cyst-wall also was adherent to the abdominal walls. There is, however, always danger of exciting peritonitis, and we only tap where the diagnosis is very doubtful.

While the diagnosis was not doubtful here, it was very doubtful as regards the extent and character of the adhesions, and I had no other method of satisfying myself but by tapping in order to discover these adhesions high up on the side and also in the pelvis. In this case, the operation was very satisfactory; but it must be remembered that every time you tap your patient, you render the possibility of operating upon them by ovariotomy more difficult. Lawson Tait has brought this out very well indeed. His theory is that you exhaust the patient by repeated tappings; you take away this enormous quantity of fluid, which is reproduced at the expense of the normal constituents of the blood; and hence when you perform ovariotomy your patient is in no condition to recover, even if you escape peritonitis. They die, he says, of asthenia.

In this case, we can give this woman relief for a few months more of her remaining life, but that is all. Had we chanced to see her in the earlier stages of her difficulty, we might have been able to save her; but as it now is, this tumor is simply crowding her out of existence. The question may then arise, Is it not better to operate in cases of this kind, with hopes of a permanent cure, than to allow them to live a few months longer, with the knowledge that death must inevitably result from their disease? This is an extremely difficult question to answer, as the patient may not be willing to run the risk of an operation, even if you are to perform one.

SUBPERITONEAL FIBROID OF UTERUS.

This patient is thirty-seven years of age, and has been married seventeen years. Ten years ago she came to me in the dispensary. I then proposed an examination, when she suddenly fainted, and on reviving she stated that she often had these attacks. She has had no children. She has had three miscarriages, one at five months, one at three months, and one at three and a half months; the last was ten years ago, after which time she came under my care. A few points in her history which I remember now are these: one being pelvic peritonitis, which she had some time ago, the result of exposure; at another time she threatened to develop tuberculosis—threatened, I say, because she had a circumscribed bronchitis at the apex of the left lung, and I believe that is considered rather a forerunner of tuberculous deposit, and with this a peculiar disposition to miscarriage, with occasional attacks of menorrhagia, with pelvic tenesmus and backache, she has lived a half-sick, half-well kind of life. She has menstruated irregularly, and quite often profusely, at one time having menorrhagia for two months. We might say of this patient that she has had something of a slight menorrhagia, at times pronounced, at other times not marked, but on the whole a disposition to hemorrhage; that she has had an attack of pelvic peritonitis, that she has all along had a great deal of pelvic pain, so that she has never been equal to ordinary locomotion; walking, standing, or sitting, for a long time past, has given her a good deal of trouble.

Now we will endeavor to ascertain what the pathological conditions are which give rise to this history. Her miscarriages have been involuntary. We sometimes find patients who have a history of a number of miscarriages; but upon investigation we find that they have been caused by the patient herself or some companion in iniquity; but in this case it was due to the organization. I will give you the physical signs in a moment. I might say now that I find the uterus high up, the os far back in the left side, so that I can reach very little of the uterus in the pelvic cavity. Now here we have an abdomen that is symmetrically developed apparently, a little fuller perhaps on the left side; this abdomen presents nothing unusual to a patient who has much adipose tissue, but in this case it is out of proportion to the rest of the body. An abdomen of this size, at thirty or forty years of age, is nothing if it corresponds with the rest of the body. In this case it does not. We will now see how much of this is adipose tissue; to decide this we raise up a fold of the abdominal wall between our hands, and measure the thickness of the fold we thus retain. In this case it is four inches; now divide this by two, and it gives us two inches, which is the thickness of the adipose tissue upon the abdominal walls of our patient.

Now I find in the region below the umbilicus an area of dulness or flatness, but above this we get the tympanitic resonance. Now besides this amount of adipose tissue, there is something else here which gives this flatness on percussion, and as I follow this around, and compress the adipose tissue, I come to a solid mass. In this region here I get flatness on percussion and a mass solid to the touch. Let us see if it is fluid; perhaps it is not solid. I find here not the slightest diametrical fluctuation; I get no wave. Let me try if I can get it with peripheral percussion, taking a small section; I do not. Let us see if I get displacement; I can displace the whole mass. Now if it was fluid, I would displace it upward or downward by pressure; but this I cannot do. I get motion of this entire mass to a very limited extent; so I have all the physical signs of solidity, or a solid tumor. So much is adipose tissue (grasping the adipose tissue in his hand), the rest is solid material. This gives you an idea of the size of this neoplasm.

Now from these physical signs I am well satisfied that this is a solid mass. There is one source of error, not marked in this case, however, and that is the apparent fluctuation of adipose tissue. This differs according to the character of the tissue; it may be almost solid, or of a jelly-like consistency, depending upon the proper amount of the elements which make up this adipose tissue. Sometimes it is so soft and yielding that it fluctuates; this puzzles us sometimes. Just bear in mind the physical signs here, and I think you will be perfectly safe in saying that this is solid material, or, if not solid, a semi-solid material, within a very dense cyst-wall. We occasionally have a thick cyst-wall containing a gelatinous material, so that the whole mass gives us all the signs of solidity; it does not fluctuate, does not yield to pressure; these, however, are very rare cases. Even in the ovarian cysts, where the contents are gelatinous and thick as glue, you will get this sense of fluctuation. In the fibro-cyst we often get that motion which simulates fluctuation so clearly that we are inclined to diagnosticate fluid when it is semisolid. Apart from these conditions, I know of nothing in the list of abdominal tumors that would be likely to deceive us.

There is, however, one other condition that would give us some of the physical signs that we have here. When I find a symmetrically developed abdomen, the question arises whether we have a pregnant uterus; for the physical signs obtained by the vaginal touch may leave us in doubt about that. The uterus in this case has entirely escaped from the pelvis, except a small portion. This, you know, is the condition in the later months of pregnancy,,and the question arises whether we have a pregnant uterus, or an enlargement of the organ from some neoplasm which produces the same physical signs. Here, in this case, we find an inelasticity about this which rather argues against gestation; almost always the pregnant uterus will yield to pressure, and sometimes after manipulating for a time, the walls of the uterus will contract; then it simulates the tense cyst or solid tumor, so that you get neither elasticity nor fluctuation. This alone, however, would not be sufficient to exclude pregnancy. The character of the cervix in this case argues against it, as it is very small; it is not enlarged and soft, like the pregnant cervix. Again, this woman has none of the signs of fœtal motion or fœtal heart-sounds, nor changes of the mammary glands. Dr. Stewart has excluded this, and I will not dwell upon this peculiarity. Then we come to the next question, What is this tumor? It is evidently connected with the uterus, as the uterus is displaced, and the cervix moves when we move the mass in the abdomen. It looks as though the tumor was on one side, and the uterus on the other, so that we have a right lateral version of the uterus, the cervix pointing a little towards the left side. When you place her on the left side, the tumor comes nearer to the normal axis of the uterus; that is a very good point in evidence of this right lateral version of the organ—fundus to the right, cervix to the left.

Now, I have but very little doubt in my mind that this is a large fibroid growth projecting from the left wall of the uterus; I believe that, because six or eight years ago I was able to make out that she had a fibroid growth, and her subsequent history agrees with the present physical signs. It has increased enormously since then, as it now extends beyond the umbilicus.

I have mentioned to you before, that of these fibroids of the uterus we have three varieties; not that the pathology of the growth changes at all: they are all alike in their hystological composition, but differ in their location. It is important to bear in mind the varieties in regard to location, as each one behaves differently. I represent upon the blackboard the uterus, composed of three sections or layers of tissue, the three colored chalks representing these as follows: from within outwards, first, the mucous membrane of the uterus, next its muscular tissue, and finally its peritoneal covering; we find the fibroid growth in this case just beneath the peritoneum; this, then, is a subperitoneal fibroid of the uterus. When the growth occurs beneath the mucous membrane, it is called submucous. The third variety is a growth within the walls of the uterus, and is called an interstitial fibroid of the uterus, because it grows in the muscular walls of the organ itself.

Here, then, we have the three varieties according to location. Now, as I have before remarked, each one behaves differently. The first one, the submucous, increases the size of the cavity of the uterus; the menstruation then becomes excessive, because you have more surface to menstruate and an increased vascularity, hence we have no affection short of malignant disease which gives the same amount of hemorrhage as this. Some authors have called this the bleeding disease of the uterus, it being so excessive sometimes that the life of the patient is threatened from loss of blood. This patient has sometimes had metrorrhagia, but it has not been excessive more than once in her whole sickness, she then having two months of constant though slight oozing.

Now, in the second or subperitoneal variety, the growth being away from the cavity of the uterus does not give rise to this hemorrhage to the same extent; the interstitial variety then holds a position between the two in regard to hemorrhage. There is much difference, you observe, between the history of each. Each history, then, aids us in making our diagnosis, and hence you cannot fail to appreciate the importance of the history in these cases. In a case like this, the menorrhagia has been so slight that it is almost certain the tumor is not submucous. There are physical signs which enable us to diagnosticate the location of the tumor. Sometimes these subperitoneal fibroids become pedunculated, and we can move them around within the peritoneal cavity, and demonstrate their attachment to the uterus.

Again, if the tumor projects from the outer surface of the uterus as a distinct nodule, it is a sign of its being subperitoneal. In using the uterine probe, if we find that the cavity of the uterus is straight, but largely on one side of the tumor, it proves that the tumor is subperitoneal or interstitial, with a marked tendency to extend outwards. On the other hand, if the canal of the uterus is deflected in a marked degree, the fact points to the tumor being submucous. If the tumor projects into the cavity of the uterus, so that the sound can be passed partially around, it is clear evidence that the tumor is submucous, and tending to become intra-uterine and pedunculated.

The modes of treating these fibroids may be briefly stated as follows: By ergot, electrolysis, enucleation, removal of the ovaries, and finally removal of the tumor, uterus, ovaries, and Fallopian tubes. Ergot gives its best results in the submucous varieties. Enucleation is employed only in the submucous tumors, when they are well within the grasp of the uterine walls, and low enough down to be easily reached. Removal of the ovaries is called for in cases which cannot be managed by the other means mentioned, and the same may be said of the two remaining methods.

FATTY ABDOMEN.

Our next case, although not coming under this class of disease, illustrates so well the liability to error in diagnosis of abdominal tumors that I now present her to you that you may especially note the condition and appearance of one of these large fatty abdomens, as simulating disease of the ovaries or uterus.

This patient is thirty-seven years of age, has been married thirteen years, and is the mother of four children. She has menstruated regularly until three years ago, and to-day presents herself to us with an abdominal enlargement, which brings her here to obtain counsel.

You will observe that the abdomen is symmetrically enlarged; there is no irregularity about it. We will now proceed to examine the patient as in the former case. It is always advisable to first make out how much adipose tissue there is upon the abdominal walls; this I have already instructed you how to determine. In this case, as you observe, if we were to remove all of the adipose tissue, there would be very little enlargement left compared to it now. We now desire to find out if there is any fluid. In this case the abdomen flattens when the patient lies upon the back; that occurs in hydroperitoneum, if the accumulation of fluid is small. Now if there is any fluid, it will be dull on percussion at the most dependent parts. The intestines would float upon the fluid, and give resonance on percussion, but not so below, at the sides of the abdomen; and here, you will observe, we get this dulness on both sides. Now, above here, we do not get a clear tympanitic resonance; but let us compare it with another that is flat or non-resonant on percussion, and you will note the difference. There appears to be a little dulness, but I believe it is due to a loaded colon. In this case we get no diametric wave on palpation, but we get an adipose wave; this is a mere surface-wave; it is not the fluctuating wave within the abdominal cavity which fluid gives. If we were to remove this adipose tissue and empty the colon, we would have an abdomen of normal size.

There is, however, one difficulty in the diagnosis of abdominal tumors that I have not been able to illustrate to you, and it is the most difficult to diagnosticate; it is that condition in which the omentum becomes enormously loaded with fat, sometimes called fatty omentum. In such cases you have evidence of fat in the walls of the abdomen, but it is not enough to account for the enlargement of the abdomen, and you can only make your diagnosis by the tympanitic resonance underneath at the sides of the abdomen; you form your diagnosis by exclusion of hydroperitoneum, ovarian cysts, etc. So you see that, while it is easy to measure the fat of the abdominal walls, it is not so easy to discover the amount of fatty tissue that may be lodged in the omentum. Fortunately this fatty omentum is rather rare, and there are not many cases that have such an amount of fat as to interfere with our diagnosis. The point of interest in this case is that it gives us an opportunity of applying the rule of exclusion in diagnosis. Sometimes, when you have a case in which there are no prominent symptoms or signs, nothing that you can lay your eye or hand upon, and yet in which there is certainly some pathological condition present, you can practise exclusion until you get down to the only thing that it can be. We tell what a thing is, sometimes, by first discovering what it is not. The diagnosis in this case is enlargement of the abdomen from fat and feces. The one can be disposed of by cathartics, the other by proper diet and exercise.

FIBRO-CYST AND SEPTIC CACHEXIA.

This patient I saw at my office a week ago, and I would very much like to have shown her to you at that time; this case is an extremely interesting one. She has that dull, pale, cadaverous look, and is extremely emaciated; in short, she has a cachectic appearance. Now, bear in mind the difference between diathesis and cachexia; the one is a latent tendency, and the other is an evidence of active disease.

The skin in this case has a peculiar, dry, ill-conditioned appearance; she has, then, evidence of some disease belonging to the class of degenerations. Now, upon examination, I find the uterus entirely out of the pelvis; I can just reach the external os, just beyond the superior strait, but I find a mass which occupies this lower zone of the abdomen, extending above and to the right of the umbilicus. I find also that this mass involves the uterus, for I can toss it up between my hands very readily. At the upper portion, it has a little elasticity; and I am inclined to think from her appearance that we have here a cysto-sarcoma of the uterus, which has been developed within the past two years, during which time she has been troubled with menorrhagia.

It is possible that I may have made a mistake, and that this growth commenced as a sarcomatous disease of the ovaries, and then grew around the uterus. About this, however, I am not positive, but I am satisfied that this is not a simple fibroid of the uterus; neither do I think it is a fibroid cyst, for at this stage they do not give rise to this cachectic appearance. This appearance, however, may be due to renal disease, or she may be a malarial subject; I am inclined, however, to believe that this is a growth from the uterus, with a malignant tendency. The point of interest to which I would draw your attention is this cachectic appearance, so characteristic of malignant disease.

We will place this patient upon the arsenical treatment for two reasons: if it is malaria, this treatment is in order; if also her disease be malignant, it is then good treatment. I would advise the use of Fowler's solution with good tonic treatment. Sometimes we can adjust our therapeutic agents when our ideas of the pathology are somewhat cloudy; we will therefore place the patient on this arsenical treatment, although I am in some doubt as to the nature of this growth.

My diagnosis is not complete in this case, and it teaches you an important lesson—viz., we are not always bound to make a positive diagnosis. The best diagnosticians are those who watch carefully their case, and then make their diagnosis subsequently: it is far better to hesitate if you have not the means of being positive. We should do as they do in law; leave room for an honorable escape if possible.

(*To be concluded.*)

ORIGINAL ARTICLES.

REMARKS UPON THE USE OF IODOFORM AS A WOUND-DRESSING,

WITH A REPORT OF CASES IN WHICH IT WAS USED.[1]

By J. EDWIN MICHAEL, M.D.,
PROFESSOR OF ANATOMY AND CLINICAL SURGERY IN THE UNIVERSITY OF MARYLAND; CONSULTING SURGEON TO THE BALTIMORE PRESBYTERIAN EYE AND EAR CHARITY HOSPITAL.

Ever since it has been known that putrefactive changes in wounds and the consequent deleterious effects on patients are due to the presence and activity of micro-organisms, it has been the aim of surgeons to procure a wound-dressing capable of preventing the presence, or destroying the vitality of these intruders. For the last fifteen or twenty years, surgical literature has been replete with suggestions and discussions relating to this subject, and although we cannot be said to have arrived at a conclusion even yet, sufficient advance has been made to revolutionize surgical procedure in many respects.

Listerism has gained many votaries in all civilized communities. It is true that many who once practised it have given it up on account of the cumbersome and complicated technique which its use entails. But the fundamental principle upon which it is based is acknowledged by all, if not in words, in the careful practice of what is couched under the specious term, "cleanliness." Moreover, carbolic acid was found to be a poison, even when applied to wounds, and had the additional drawback of irritating the surfaces with which it came in contact. Other substances were brought into requisition. Thiersch introduced salicylic acid, and demonstrated its value as a germ-destroyer. Volkman advanced the claims of thymol, and met with much success in its use. Other surgeons introduced other substances, and naphthaline, corrosive sublimate, iodoform, bismuth, and other antiseptics have their advocates.

---

[1] Read by invitation before the Cecil County Medical Society, July 11, 1883.

We aim at perfection, though we may never reach it, and the voices of those who sound the praises of the new discoveries scarcely die away before the warning cries of the critics who discover inefficiency or danger fill the air. But experience in this, as well as in other matters, must be our guide, and we may hope that, in the contest for supremacy, we may at least learn what is best, even if we may not reach perfection.

Being prepared to contribute my mite to the general fund, I have made some experimental study of one of these agents—viz., iodoform—and propose in this paper to give some account of its introduction into surgical practice; its use by others, and to lay before you the results of my own experience with it.

The physical properties and chemical nature of iodoform are sufficiently well known to make any reference to them unnecessary. It has been used in medicine for a number of years as a valuable remedy in certain forms of syphilis and tuberculosis, and it has received deservedly high praise as a local application to ulcers, venereal and simple, and to certain conditions in eye, ear, and throat disease. It was, in fact, its efficacy in checking certain tuberculous processes which led to its introduction as a wound-dressing. Prof. von Mosetig,[1] Moorhof, in Vienna, to whom the credit of its introduction is due, first used the drug in the treatment of fungosities in tuberculous joint-disease, and was struck not only with the manner in which it controlled the fungous process, but also with certain other peculiarities. He observed that in cases in which it was used, it acted as a local anodyne; that the wounds remained perfectly sweet, and that the discharge was reduced to a minimum. This led to the conclusion that iodoform would be a practical and convenient substitute for Listerism, and von Mosetig began to use it in dressing ordinary operative wounds.

After a long course of experimentation, he announced his discovery to the world, and expressed the most enthusiastic admiration for the antiseptic virtues of iodoform. He says: "In the light of my former experience, collected with great care and accuracy, I do not hesitate to say that not only is iodoform a safe specific against local tuberculosis, but also that it acts as an antiseptic in non-fungous surgical lesions, and accordingly deserves a very prominent place among the antiseptics so far known."

After nearly three years' experience, Prof. v. Mosetig comes to the following twelve conclusions. As the first and second relate exclusively to tuberculous fungosities, they will be omitted.

3. For non-fungous wounds, iodoform has shown itself the safest antiseptic, since, on account of its difficult solubility in the tissue-fluids, it remains long in the wound, and develops a continuous antiseptic action.

4. Iodoform locally applied in moderate quantity is not dangerous to the organism, although it is in part absorbed, and eliminated by the kidneys; indeed, in many diseased organisms, this transient presence of the drug in the circulation may be of great use.

5. The immediate action of iodoform in fresh wounds is anæsthetic; later it promotes granulation, and absolutely prevents all septic trouble in the wound.

6. The progress of the wound is most frequently afebrile; sometimes, however, there is exalted evening temperature, though not of septic character, for the first few days. Iodoform sprinkled between wound-surfaces does not prevent healing by first intention.

7. In iodoform dressing, as in all other methods, a way must be provided for the escape of the wound secretion. The soaking of secretions through the dressing does not alter its antiseptic character; only elevation of temperature in the further progress of the wound, which points to retention of secretion, absolutely demands change of dressing for inspection of the wound. Where there are no febrile symptoms (except in the first few days), soaking of the secretions through the dressing indicates a change for the sake of cleanliness only.

8. Traumatic erysipelas with iodoform dressing is very rare; when it occurs, retention of secretion is the cause.

9. Iodoform is so potent an antiseptic that the simultaneous use of any other is unnecessary. For washing the wound, therefore, clean water is all that is necessary; and the use of antiseptic solutions, such as carbolic, boracic, and salicylic washes, although useful, are not absolutely necessary. Cleanness of the part operated upon, of the instruments, and of the hands of the operator and assistants are self-evident requirements, as also gentleness of manipulation and quiet of the operated part.

10. Iodoform dressing is the cheapest, safest, most permanent, and easiest applied of all the hitherto known antiseptic dressings. The materials for the dressing can be found anywhere, and the iodoform powder, as well as the iodoform gauze, may be kept for years without losing any of its virtues.

11. Iodoform allows the use of the antiseptic process after operations in the mouth, in or near the rectum and bladder. surgical procedures in regard to which a thought of complete antisepsis could heretofore scarcely have been entertained.

12. The deodorization of iodoform by Tonka bean allows its use even upon individuals very sensitive to its odor.

Encouraged by the success of von Mosetig,

---

[1] Wiener med. Woch., 1880, xxx., 1173, 1202, 1254, 1340, 1392.

Mikulicz, and Wölfler, Billroth's assistants, Gussenbauer, Leisrink, and many others began to use iodoform dressing, and were rewarded by astonishingly brilliant results.

Mikulicz[1] reports the results reached in the immense clinic of Prof. Billroth as follows: "Of fifty-three great wounds, forty-nine pursued an aseptic course. There were but two cases of erysipelas, one in a person who had cheesy glands removed, the other in a case of cancerous infiltration. Innumerable small operations, nerve-stretching, etc., healed mostly *per primam.* The conclusions which Mikulicz reaches are, if possible, more favorable than those of von Mosetig, though set forth more briefly.

1. For all conditions in which the direct application of an antiseptic to a wound-surface is indicated, iodoform is an excellent remedy, and preferable to all others hitherto used. 2. The iodoform dressing completely takes the place of the Listerian, with additional advantage of greater simplicity and increased safety. 3. Iodoform dressing assures asepsis under circumstances in which it has been hitherto impossible. 4. In wounds already septic and in ulcers, iodoform generally purifies them more quickly and safely than any other antiseptic, and without irritating the tissues. 5. Iodoform acts specifically on syphilitic, scrofulous, tuberculous, and lupous infiltrations.

The results and conclusions of others of the earlier observers agreed in the main with those already quoted, and iodoform was used in the most reckless manner. Abscess-cavities were packed with it, joints were filled with it; large operative wounds were covered thickly with it. Some surgeons did not hesitate to put 150 to 200 grm. into a wound. This recklessness could lead to but one result, and cases of iodoform poisoning began to be reported. Dr. A. Henry,[2] assistant to Prof. Fischer in Breslau, reported two fatal cases. In one, a patient fifty-seven years of age, resection of the elbow was done, and 150 to 200 grm. of iodoform were packed into the wound. Death occurred on the fifth day, with symptoms of cerebral character, hebetude, etc.; nausea, rapid, weak pulse, and sunken belly. The autopsy showed fatty heart, liver, and kidneys. In the other case, an abscess at the knee was opened, and between 100 and 150 grm. of iodoform packed in. The patient died on the fifteenth day with symptoms like those of the previous case, except that there was no vomiting. The autopsy was negative. Others reported cases of poisoning, some transient, some fatal, and although the number of cases of poisoning was very small, especially in view of the immense quantities of the drug applied, surgeons became alarmed, and there was a decided revulsion of opinion in reference to the new treatment.

A glance at the accounts of the cases of poisoning serves to indicate that the old and debilitated, especially those with weak hearts, are particularly susceptible to the deleterious influence of iodoform, and warns us to be especially prudent with its use in such cases. And since, as in the case of most of our other valuable medicines, there is sometimes a notable vulnerability to iodoform, we should be always on the look-out for symptoms which indicate intoxication. These warning symptoms refer usually to the head, heart, or stomach, or to all three combined. When there is intense headache, hebetude, excitement, hallucinations, nausea, with or without vomiting, or very rapid and feeble pulse, it is the part of wisdom to immediately change the dressing, wash out the wound, and substitute some other mode of treatment. I believe with close attention to this matter, there is practically little or no danger in the use of iodoform as a wound-dressing.

Iodoform may be used in a variety of ways. The most common and, generally speaking, the best is in the form of powder, or in the crystals. The operation being completed, the hemorrhage controlled, and the wound irrigated with pure or carbolized water, the powder should be sprinkled on with a spatula from a pepper-box, blown on with an insufflator, or even poured on from a bottle. Some prefer to press it into the wound with a spatula, or rub it into the surfaces with the fingers. The object is to bring it in contact with the wound-surface, and it matters little how this is done. In small wounds it may be used freely; in large ones, we must remember the possibility of poisoning, and be more cautious. The more conservative authorities recommend that the quantity should be limited to ʒiij. I have not hesitated to use ʒiv–ʒvss in many instances. The other details of the dressing must depend on the nature of the wound. Sutures or drainage-tubes may be used or not, though it must be remembered that iodoform checks secretion, and many wounds in which drainage would be necessary with other forms of dressing will not require it with this. A layer of cotton, oakum, lint, or other convenient material, covered with macintosh, gutta-percha, tissue, or oil-silk, with a bandage, will complete the dressing. This may be left *in situ* until high temperature (after the second day), soaking through of secretions, pain, or other symptoms call for a change of dressing. I have left a dressing of this kind thirteen days, with none but the best results.

Iodoform gauze may be made very easily, and kept indefinitely. A good formula is as follows: Dissolve ʒxxiij of resin in f℥xxxvj of 94 per cent. alcohol, and add f℥iss of glycerine. In this fluid soak 6 m. (about 7 or 8 yards) of gauze (tarlatan), and, when it is about half dry, sprinkle ʒxiij of pulverized iodoform over it. The gauze may be applied to wounds, as carbolized or other gauze, but it is particularly useful in the treatment of wounds in the mouth, in or near the rectum, and in other parts where the powder cannot be conveniently used. An emulsion of any required strength may be made with castor oil or other bland vehicle, and is useful for injection into joints, abscess-cavities, etc. Suppositories made with cocoa-butter are sometimes useful, and a solution in ether may be applied in spray.

Iodoform is certainly a very valuable addition to our list of antiseptics, and presents some points of interest well worthy of study. Its portability and the simplicity of its application are points in its favor. Its use reduces the dressing of a wound to the minimum of trouble, and does away with all the complicated details of Listerism without losing any of its advantages. We can attain all that the antiseptic treatment has to offer wherever we can carry a bottle of the powder, and procure a bat of cotton, and for the country surgeon especially it is invaluable. These qualities also peculiarly fit it for the demands of military surgery, and I have no doubt that in the next war it will play a prominent part, even if, as has been suggested by a German surgeon, every soldier is not compelled to carry in his belt a bottle of the drug for the treatment of his own wounds. Iodoform is all-powerful in the presence of bad smells, and acts not merely by the substitution of its own instead, but by destroying them. No putrefaction can go on in a wound dressed with it. Wounds dressed with it, without change for days and even weeks, are found sweet and clean, and putrid wounds soon lose their fetor in its presence. Its power of decreasing secretion is of great importance in many cases, so much so that with it the drainage-tube, which would otherwise be necessary, may be dispensed with. It is without doubt the most powerful antisuppurative agent known. An important point in its favor is its local anæsthetic effect. Different in this respect from many other antiseptics, it soothes where they irritate. Nevertheless, it exercises a gently stimulant effect, and is equal, if not superior, to any agent known in transforming pale, flabby, exuberant granulations into those of a florid, vigorous, healthy character. The length of time a wound may be left without change should not be passed over without proper consideration. There is a great difference both to patient and surgeon as to whether a wound is dressed every day or twice a day, or once or twice a week, and the latter is the rule where iodoform dressing is used.

---

[2] Deutsche med. Woch., 1881, p. 461.

Against these manifest advantages we must consider the objections. The drug is rather expensive when we speak of it by the ounce, but it must be remembered that a little of it goes a long way, and, once applied, it remains for a long time, so that in the main it will be found to cost but little more than dressings ordinarily used, and by no means as much as the Listerian dressing. Its odor is intensely disagreeable to some, though for myself I must confess that I have the bad taste to rather like it. But it can be masked by a drop or two of the oil of bergamot to the drachm, or, as von Mosetig prefers, by keeping a Tonka bean in the bottle with it. I apprehend that the only real objection to iodoform is its danger, and we are not yet far enough advanced in its use to properly estimate its amount. I am inclined to think we can reduce it to a minimum, if we cannot entirely eliminate it, by watchfulness and care. The latest testimony I can find on the subject is that of Dr. H. F. McGill,[1] of Leeds, England, who concludes, after a six months' use of the drug, as follows: "An enlarged experience may possibly make me change my opinion in regard to the value of iodoform; at present I consider it a safe and reliable antiseptic."

My first experience in the use of iodoform as a wound-dressing occurred last summer. I was called on to amputate a thigh under circumstances of rather unfavorable character. The patient was a man of about sixty years of age; the weather was hot and disagreeable, and I had to operate by candle-light. I concluded to use iodoform as the most convenient dressing. The face of the stump was freely sprinkled with it; the skin-flap sutured, and the ligatures brought out at the lower angle. On the thirteenth day, I met my patient walking on crutches, with the stump healed, except at the angle where the ligatures came out. He had no fever or other bad symptom during his cure.

When my hospital service began in January last, I determined to give the drug a fair trial, and I have the pleasure to-day to lay the result before you. I take this occasion to express my thanks to Dr. Ralph Steiner, Assistant Resident Physician of the Maryland University Hospital, to whose zeal and care I am indebted for full notes of all the cases treated, from which notes this report is abstracted.

Case I.—G. A. F., aged 23, railroad employé; large axillary tumor on the right side (round-celled sarcoma), about four pounds in weight. The operation left the axilla pretty clean, and the arteries and veins exposed, etc. The whole wound-surface was sprinkled with iodoform in powder, a drainage-tube was placed in the lower angle, and silver wire sutures were used. A pad of oakum and a bandage completed the dressing. The operation was done January 26th, and on the 27th there was slight nausea during the night, no pain; temperature 99°; pulse 98. 28th: temperature 100°; pulse 100. 29th: temperature 101°; pulse 100. 30th: temperature 98.4°; pulse 100. 31st: temperature 101°; pulse 88. The wound was dressed and the tube removed. The discharge was found to be scant. The wound was washed out, dusted with iodoform, and covered, as before, with oakum pad and bandage. From this time the wound was dressed about every fourth day, and the favorable progress of the case was uninterrupted. He was discharged, with a small superficial granulating wound, at the end of the third week.

Case II.—A. Davis, colored, aged 43, laborer; caries of the carpus; amputation at wrist; dressed with iodoform as in the above case. On the second day there was slight pain; temperature 101°. From this time there was neither high temperature, pain, nor other indication for removing the dressing. It was removed, however, on the thirteenth day, and the wound was found united in great part. A few fistulous openings, however, remained, and upon subsequent probing it was found that the bone disease had invaded the lower end of the radius, and another operation became necessary, which will be reported below.

Case III.—Mrs. C. A., aged 50; amputation of breast (left side) and removal of axillary glands, necessitating dissection of the axilla. The patient was weak and nervous, with rapid, weak pulse before the operation. The wound was dressed with iodoform, oakum, and bandaged, with drainage-tube in the axilla. Second day: as there had been some oozing and discharge (serous) from the wound, it was dressed as before; temperature 101°; pulse 150. Third day: temperature 100°; pulse 130. Fourth day: temperature 99.3°; pulse 130. Fifth day: the patient was weak and semi delirious; nauseated; pulse was more rapid and weaker; ordered the iodoform removed and carbolized oil substituted. From this time, however, the patient grew weaker, the cerebral symptoms becoming more aggravated, and died comatose on the eighth day after the operation. (This case will be discussed more in detail below.)

---

[1] Lancet, May 26, 1883.

CASE IV.—Fritz B., aged 10; amputation of thigh (middle-third). The patient's leg had been crushed five days before. He was brought into the hospital with a leg gangrenous to the knee, and his general condition was extremely feeble. The amputation was done, as a forlorn hope, by the circular method. The wound was dressed with iodoform, oakum, and bandage. Second day: temperature 102°; pulse 150, very weak. Third day: temperature 101.4°; pulse 140. From this time the patient gradually improved until the eighth day, when a discharge having appeared through the dressing, it was changed for the first time. The outer half of the wound was found healed by first intention. From the inner and lower angle there was some bloody serous discharge. The wound was washed out and dressed as before. On the ninth day tetanus developed, and, although the patient recovered fully from both that disease and the amputation, the remainder of the temperature record was made worthless for the purposes of our present study.

CASE V.—Harriet B., colored; small axillary tumors secondary to cancer of the breast, which I removed four years ago. The operation involved considerable laceration of the axillary tissues. The wound was dressed with iodoform, oakum, drainage-tube, and bandage. The dressing was left *in situ* for a week, during which time the highest temperature developed was 99.4°, on the evening of the second day. The drainage-tube was then removed, and two days later the patient was discharged, with a very small superficial granulating wound.

CASE VI.—Mrs. S., aged 58; cancer of cicatrix, from amputation of breast and several axillary tumors. The patient was very stout. The incision was thirteen inches in length. All cancerous parts, as well as axillary glands, were removed. The wound was dressed with iodoform, oakum, the tube, and bandage. The highest temperature, 100.1°, was on the evening of the fourth day, when the dressing was removed for the first time. Some pus was retained in the axillary portion of the wound. About two-thirds of the incision healed *per primam*. The wound irrigated. Fifth day: temperature 99°. After the fifth day the patient was subject to slight mental aberrations, probably due to mild iodoform-poisoning, but nevertheless made a good recovery.

CASE VII.—John P., aged 55, laborer; amputation of arm (middle). The wound was dressed with iodoform, oakum, and bandage. Second day: temperature 100.2°; pulse 112. Third day: the patient died of traumatic pneumonia, due to fracture of two ribs received in the same injury which made the amputation necessary. One of his legs was also severely crushed.

CASE VIII.—Lizzie H., colored, aged 25; axillary glands, due to cancer of the breast, were removed five years ago. All hardened glands that could be found in the axilla were removed. The wound was dressed with iodoform, oakum, and bandage — no tube. Second day: temperature 103°; pulse 90. Third day: temperature 103°; pulse 110; the dressing was removed and the wound was doing well in every respect. The examination, however, showed localized pleuritis, which accounted for the high temperature and pain complained of, and also vitiated the record as far as the temperature is concerned. . The patient, however, did well, and was discharged at the end of the second week with her wound nearly healed.

CASE IX.—A. D., aged 43, colored (same patient as Case II.); amputation of forearm. The stump was dressed with iodoform, oakum, and bandage. On the evening of the third day the temperature was 100.2°, and he complained of pain. The dressing was removed, and a somewhat abundant thin serous discharge was found. From this time it was dressed daily and irrigated with carbolized water. On the evening of the fifth day the temperature reached 102°, which was the highest point; afterwards everything went well and the patient made a good recovery.

CASE X.—Martha E., colored, aged 37; breast amputated and axilla cleaned out. The incision was eleven inches long. The wound was dressed with iodoform, oakum, and bandage, with tube. The highest temperature was 101.4°, on the evening of the second day. The dressing was removed on the sixth day, and more than half of the incision had healed. Three-fourths of the tube were cut off; the discharge was very scanty, and she left the hospital nearly healed on the twelfth day.

CASE XI.—Henrietta M., aged 20, colored; large osteo-enchondroma of the neck, in apposition to the angle of the jaw. It was removed by incision and finger dissection. and dressed with iodoform, oakum, tube, and bandage. The highest temperature was 102°, on the evening of the second day. The dressing was changed on the third day, very little discharge, tube removed. From this time there was uninterrupted favorable progress, and she left the hospital on the twelfth day.

CASE XII.—Harriet H., aged 67, colored; amputation of the breast and removal of the axillary glands. The wound was dressed with iodoform, oakum, and bandage. As there was considerable discharge on the second day, the dressing was changed. The highest temperature was 101.1°, on the fourth day. This patient was very feeble and required tonic treatment, but suffered from no surgical accident. She left the hospital at the end of the third week, with the wound practically healed.

Case XIII.—Antonin B., aged 43; traumatic hematocele of the tunica vaginalis, right side, with laceration of the testicle; sac laid open; clots and disorganized blood turned out; sac irrigated and well sprinkled with iodoform; cotton-pad and bandage completed the dressing. Third day: temperature 102°; dressing removed, and some retention found. Dressing changed daily, as the discharge was abundant. No septic or other trouble developed, and the patient left the hospital on the eighteenth day, with a wound only half an inch long, and granulating satisfactorily.

Case XIV.—Patience S., age 51, colored; large atheromatous tumor of back, removed by elliptical incision; wound dressed with iodoform, cotton, and bandage; highest temperature 102.2°, on evening of second day. Dressing was, however, not removed until the fifth day, when all the wound, except the lower angle, was found healed *per primam.*

Case XV.—John H., age 27; sequestrotomy; old necrosis of lower end of femur; involucrum opened with chisel and mallet, and sequestrum, about five inches long, removed in pieces; wound irrigated, and about sixteen grm. of iodoform poured into it. Oakum and a bandage completed the dressing. Highest temperature 101.4° on second day. The dressing remained *in situ* five days, when, as the discharge was abundant and foul, on account of the dead bone, it was changed. This patient spent but two days in bed, and the remainder of his progress while he remained in hospital was afebrile. He left on the ninth day, preferring to dress his wound at home.

I have also used iodoform on a number of interesting cases in private practice, of which I have kept no record, and on a large number of trivial cases which I have not thought worthy of consideration. I have given the more important cases in which the drug was used, and although the number is too small to warrant any general conclusions, the report may serve to aid us somewhat in forming an estimate of the iodoform treatment. For my part, my experience with it thus far encourages me to go on, at least, until I find something that will produce the same good effect without the danger of poisoning.

The summary of my results is as follows:

Greater amputations,	4
Sequestrotomy,	1
Axillary tumors,	4
Amputation of breast and axillary glands,	3
Atheroma of back,	1
Tumor of the neck,	1
Hematocele laid open,	1
Total,	15

In these fourteen greater operations, excluding atheroma of the back as rather a small matter, there was seen no septic trouble whatever. The highest temperature reached was 103°, which occurred upon the supervention of a pleuritis in a patient whose surgical condition was excellent. There were two deaths. One of them—VII.—occurred in a man who had been driven through a brick wall by a locomotive, and came to us with an arm crushed to pulp; collar-bone and scapula broken; two ribs fractured, and a mangled leg, besides probable internal injuries. Amputation was done as an act of humanity, to relieve shock and diminish pain, and produced the effect expected. No hope was entertained of recovery. The other death—III.—is far more interesting. I look upon this case as one of iodoform-poisoning. It will be observed in referring to the record that, upon the supervention of symptoms indicative of intoxication, I immediately ordered a change of dressing. I am prepared to confess that I was very much shocked when I saw the patient the next day to find that she was worse, instead of better, and greatly chagrined that efforts to stimulate produced no effect. It was only after the patient was dead, upon investigating the case, that I learned that the student whose duty it was to dress the wound had not seen the order to change and irrigate in the ward-book, and so had continued to dress the wound with iodoform until the day of the patient's death. I believe that if my order had been carried out, this patient would, in all probability, have been counted among the successful cases. I have had one other case besides the one mentioned in the report (VI.), in which, in an old woman with a large ulcer, which was being treated and (very successfully) with iodoform, symptoms of intoxication developed. The patient became weak, and complained of constant nausea. Change of treatment promptly relieved the symptoms.

My experience seems to justify the following conclusions in regard to iodoform as a surgical dressing:

1. It is a most valuable and convenient dressing, possessing great antiseptic power, and being perfectly simple in its application.
2. Its local anæsthetic power adds to its other advantages as a wound-dressing.
3. It decreases secretion in wounds, thereby making dry and infrequent dressing possible.
4. It does not prevent healing *per primam.*
5. It is dangerous, and should be used with great circumspection, especially in old and debilitated subjects and those with weak hearts.

246 Madison Avenue, Baltimore.

LEAD-POISONING FROM CANNED FOOD.

By WILLIAM E. MAGRUDER, M.D.,
of Olney, Maryland.

I have under my care at this time a young lady, suffering from chronic lead-poisoning, whose case is interesting, both because it has presented during its progress so many of the phases of the poisonous effects of lead, as well as from the source whence the poison was introduced into the system.

In this case, there have been the colic, arthralgia, and paralysis, involving first the extensors of the wrist, and then those of the lower extremities, and extending also to the flexors of both. The lead-cachexia was well marked, and the bluish line on the gum very distinct. The electric sensibility was much lessened, and the contractility to both faradic and galvanic currents was for a time entirely lost in the lower extremities, and very much lessened in the upper. The atrophy of the paralyzed muscles was also well marked. The young lady, though much improved, will probably never entirely recover. The case was also seen by Dr. C. G. Stone, of Brightwood, D. C.

I will not further allude to the symptoms of the case, though some of them were of great interest, as my object in writing is to call attention to the source whence the lead was introduced into the system, and to some observations I have since made in regard to the danger of poisoning from the same cause. After much trouble, I traced it to the use of corn put up in tinned cans by a recipe that required the use of tartaric acid. I tested the contents of several cans, and detected the presence of lead. This must have been derived either from the coating of the cans or the solder, or both.

Upon applying a drop or two of nitric acid to the surface of the can, allowing it to dry, and adding a solution of iodide of potassium, there was found the characteristic yellow spot. I then tested with the same test a number of cans in which food had been preserved, and found in all evidence of the presence of lead. Dr. Onderdonk, of St. James's College, Md., tested, at my request, a number of scraps of tin of which cans are made, and only found two which did not show its presence.

Dr. Dorsh states (*Chicago Med. Journal and Examiner*, Sept. 1878) that of a large number of specimens of tin plate, tinned cans, and other culinary articles examined by him, he found in almost every instance an alloy with lead, and it was often in large quantities.

These observations go to show that much of the coating upon the cans is not pure tin, but an alloy with lead. We are not as yet in possession of any facts which show tin as forming any compounds with the vegetable acids which give rise to poisonous effects, either acute or chronic, but we do know that lead forms such compounds. Now, if further investigations show that most of the cans used for canning are coated with an alloy of lead and tin (which is more readily oxidized and dissolved by acids than either metal by itself), what is more probable than that there should be injurious effects from this source?

I have a letter from Dr. Thomas Antisell, Principal Examiner of Chemicals in the Patent Office, in which he makes the following statement: "It is well known that all commercial tin is alloyed with lead, even up to the grade known as pure tin-foil, and the manufacture of tinned cans for the canned-food industry must place the food so preserved in the condition most likely to contain lead salts mixed with the organic matter; this is particularly liable with canned fruit." I have also a letter from Prof. Wormley, of the University of Pennsylvania, to my friend, Mr. C. Farquhar, who, at my request, had made inquiries on the subject, in which he says: "The use of canned fruits has, in a number of instances, been attended with the results you describe."

In *The Philadelphia Medical Times*, for May, 1874, a case of poisoning is reported from this cause. In *The Quarterly Compend. of Medical Science*, July, 1883, there is an account of an outbreak of lead-poisoning among 150 men of a regiment in the Southern Tyrol, one case ending fatally, and forty-five requiring to be treated in hospital, besides others who were not disabled for duty. The cause of the outbreak was traced to the tin-lined copper vessel in which their food was cooked, the coating of which contained lead. This shows the danger of poisoning from the coating used in tinning. There are a few other cases recorded to which I might refer as bearing upon the subject.

When we consider how much canned food is consumed, we should expect to find reports of a very large number of cases of poisoning from this source, if lead is present in the coating of the cans. But such is not the case. Very few, as far as I have been able to ascertain, have been reported. This may be owing to the fact that only a comparatively small number of physicians report cases. It may also be due to the fact that many minor forms of lead-poisoning have not been recognized and treated as such. Now there is no difficulty in diagnosticating a case of well-marked lead-poisoning, but it is not so with slighter cases. Several other members of the family in which my case occurred complained of a bad taste, pains in limbs, general malaise, numbness of the hands and wrists, etc., which would not have been ascribed to that cause had not my attention been called to them in the other case. I found then the characteristic blue line on the gums. The first cases which occurred among the soldiers of Southern Tyrol, reported above, were treated as muscular rheumatism.

How many physicians who have not had their attention specially called to lead-poisoning, would recognize as a mild form of "lead encephalopathy" such a case as described by Dr. Hammond, thus:

> "The patient suffers from headache, vertigo, and various other abnormal sensations, such as fulness and constriction, and at the same time is incapable of much intellectual exertion without suffering an increase of his physical symptoms. His mind is irritable and depressed, and his sleep is generally disturbed with unpleasant dreams. The digestion is generally deranged, and the whole appearance may be cachectic . . . . This condition may undergo no further development, but it is often the precursory state of the more severe form of the affection."

Dr. Anstie, in his treatise on *Neuralgia*, uses the following language:

> "Lead poison sometimes enters the system continuously, for a long period, but in proportions too minute to produce the effects which we identify as an attack of lead-colic . . . There is a minor degree in which it may happen that the local affection (owing, I believe, to a less extensive deposit of lead in the bowel) does not reach the decidedly paralytic stage; the state then is one of irregular and painful spasms of individual fibres (quite possibly intermingled with paralysis of a few others), and the practical result is irregularity of evacuation—now diarrhœa and again constipation—and the frequent recurrence of twinges of pain that

are easily mistaken for abdominal neuralgia. Such symptoms as these are nearly always found to have occurred, if proper inquiry be made, in those examples of chronic lead-poisoning in which the toxic process goes on to the development of epilepsy, or marked symmetrical paralysis of the wrist-extensors, without the patient ever having suffered an attack of ordinary colic. In these slow and insidious cases, the constitutional affection may not have reached the height at which the complexion and general aspect of the patient suggest metallic poisoning, and the case may present very neuralgic-like features . . . It is therefore an excellent rule, in all cases of chronic, recurrent, spasmodic pain in the abdomen, especially in men, to investigate the possibilities of lead-poisoning, and if the slightest suspicious appearance of the gums be found, this track of inquiry must be followed up exhaustively before we abandon the idea."

Naunin, in Ziemssen's *Cyclopædia*, vol. 17, page 626, says:

"Frequently, poisoning of a mild grade is said to be caused by eating acid or fatty articles of food which have been kept in tinned vessels, owing to the solution of the metal. It is to be remembered, however, that tin is frequently contaminated with lead, copper, and arsenic, or that alloys of tin and lead are used instead of ostensibly pure tin. Thus, the so-called rose tin (Bohemian tin) is said to contain as much as ten per cent. of lead."

In the Report of the Court of Inquiry on the loss of the Arctic steamer Jeannette, I find there statements which, I think, still further confirm the views expressed.

On page 30, Lieut. Danenhower, in answer to this question by the Court, "Did the character of the provisions supplied to the Jeannette cause sickness at any time?" said, "In May, 1881, a number of the people became affected with stomach disorders, which were attributed to tin-poisoning. It had been observed that the inside of the tomato cans had turned dark, as though acted upon by the acid. . . . The tomatoes were marked Red Cross brand, and were excellent in quality most of the cruise. They had been subjected to two winters' and two summers' exposure."

On page 36, in answer to a question by the Judge Advocate as to the physical condition of the men when landed on the ice, June 1, 1881, the same witness said, "The physical condition was good, with the following exceptions, viz.: Lieut. Chipp was disabled and prostrated by what was supposed to be tin-poisoning. . . . A number of men, among whom were seamen Kuchne, coal-heaver Lauterbach, and the steward, Charles Long Sing, were also affected by the tin-poisoning, and were prostrated a few days later."

I have no doubt that the so-called "tin-poisoning" was really lead-poisoning, resulting from the use of cans coated with the alloy of tin and lead.

I therefore believe that if the possibility of poisoning from this source were kept in mind and investigated, and observations made in that direction, many cases would be recognized as such, and light thrown on many obscure ones that have puzzled us.

In the *American Chemical Journal*, vol. 14, No. 6, there is an article on the action of vegetable acids on lead and tin, where the author's observations in regard to the purity of tin and the danger of poisoning from canned food, differ from what is stated above. I have not the article at hand to quote from, but will close mine with the hope that a thorough investigation may be made into the subject by those best qualified to do so.

August 13, 1883.

THE SPLANCHNICS.

BY ISAAC OTT, M.D.,
OF EASTON, PA.

It is well known that Pflüger[1] discovered that these nerves inhibit intestinal movements. He found that when the electrodes are inserted about the fifth and eleventh dorsal vertebræ, that a faradic current sent through them arrested the peristalsis of the small intestine, but did not affect the larger one. It has also been shown by Keuchel that large doses of atropine paralyze these inhibitory nerves.[2] In another paper[3] I have tried to uphold the theory that besides the intestino-inhibitory we also have an intestino-motor apparatus, and that some drugs excite the inhibitory and others the motor apparatus of the intestine. In this paper I shall still further adduce facts in support of the preceding theory by a study of the action of the same drugs on the splanchnics.

Method: Rabbits were etherized by the subcutaneous use of the anæsthetic, then the drug injected subcutaneously, and Ludwig's needle electrodes inserted into the fifth and eleventh dorsal vertebræ. The abdomen was opened, and the intestines covered with a towel wet with a one-half per cent. salt solution heated to 98° F. The room, during the experiments, had a temperature ranging between 90° and 98° F. When the intestinal movements were active, a strong faradic current from Du Bois' inductorium was sent through the electrodes, and the effect on the peristalsis noted. The reaction of the intestine was always tested by the salt crystal according to the method of Nothnagel. The salt always causes a wave of contraction running towards the pylorus. With nicotine and muscarin, the salt causes a wave of contraction upward and downward from the crystal. When a milligramme of atropine was given subcutaneously, in about ten minutes the salt-reaction failed, and when the splanchnics were irritated the peristalsis was arrested. If now .0005 gramme of the salicylate of eserin was given to the same animal, the result was the same, except the salt reaction is present.

It is not so easy to find the intestine in active movement, when small doses of atropine are given, so as to judge of the influence of the splanchnics. If, however, a larger dose of atropine, .004 gramme, is given, then, as Keuchel has already proved, the irritation of the splanchnics fails to arrest peristalsis, the bowels respond again to the salt. If morphia in small doses is given, the salt-reaction fails, as Nothnagel noted, but the splanchnics are still active when irritated. If nicotine is given to the same animal, the salt-reaction runs in both directions, and the splanchnics are still active for a period, till large doses are given, when they do not inhibit. It was also noted that morphia, when followed by a moderate dose of nicotin, kept the bowel free from the tetanic spasm of the latter drug, as happens when it alone is given. In the one case, the bowel is relaxed, in the other contracted. If muscarin is given subcutaneously the salt-reaction spreads in both directions and the splanchnics are still active. If a small dose of eserin is given the splanchnics are active when the peristalsis is active, later they seem to become weaker. If large doses of morphia sulph., .2 gramme, are given subcutaneously, the salt-reaction is present and the splanchnics are nearly absolutely paralyzed. It is possible with the eserin, nicotine, and muscarin that they so excite the intestino-motor ganglia that the splanchnic inhibition is not able to overcome it when large doses of the drugs are given. It is certain that nicotine, eserin, and muscarin do not excite the peristalsis by a paralysis of the splanchnics, as large doses of atropine and morphia do.

---

[1] Ueber das Hemmingsnervensystem für die Peristalsis den Bewegungen des Gedarme, Berlin, 1857.

[2] Das Atropin und die Hemmingsnerven, Dorpat, 1868

[3] New York Medical Journal, 1883.

These experiments lead to the conclusion that drugs act on the intestino-motor and intestino-inhibitory apparatus. That with the inhibitory drugs, atropine and morphia, in small doses the splanchnics are active, and with large doses of the same drugs they are paralyzed. That with the intestino-motor drugs, nicotine, muscarin, and eserin, the splanchnics in the beginning are not paralyzed by small doses, and that large doses of nicotine and eserin greatly weaken them.

It might be supposed that all these drugs act on the muscular fibre, and thus produce these peristaltic changes, for Dr. Gaskell has shown that muscarin arrests the apex of a frog's heart, which contains no ganglia. Whilst I do not exclude a partial action on other parts of the intestine, yet the active peristalsis must certainly have some other apparatus than the muscular fibre to depend upon. I feel quite confident that the ganglia of Meissner, Auerbach, and the isolated ganglia of Klein, play the main *rôle*.

To one who has microscopically examined, by the gold method, these ganglia, their large number and extensive ramifications will make the theory of nervous origin seem a quite reasonable one.

Experiment I.—Rabbit: Etherized, received .001 gramme of atropine subcutaneously. In twenty minutes abdomen opened, no salt reaction present. After watching intestinal peristalsis for some time, a strong faradic current was sent through the electrodes and the peristalsis arrested. Then .0005 gramme eserin was given subcutaneously; still irritation of the cord caused arrest, even when the salt-reaction was present.

Experiment II.—Rabbit: Etherized, .02 gramme morphia subcutaneously. In twenty minutes the salt-reaction failed. Spinal cord irritated, and the intestinal movements were arrested. Then .0005 gramme eserin subcutaneously, after which the intestine responded to salt. Irritation of cord arrested the movements.

Experiment III.—Rabbit: Etherized, received .001 gramme atropine subcutaneously; salt-reaction not present; irritation of cord arrested peristalsis; .004 gramme atropine given. In about twenty minutes afterwards the salt-reaction was present, and irritation of the spinal cord failed to arrest the movements.

Experiment IV.—Rabbit: Etherized, received, subcutaneously, .015 gramme morphia; salt-reaction was not present; irritation of spinal cord arrested peristalsis. Then 1 gtt. of nicotine given subcutaneously. In twenty minutes salt-reaction marked; faradic irritation arrested the intestinal movement. Another drop of nicotine was given subcutaneously; salt-reaction in both directions; faradic irritation had less and less effect, till it failed to arouse the inhibition.

Experiment V.—Rabbit; Etherized, received 1 gtt. muscarin sulph. subcutaneously; salt-reaction present in both directions; faradic irritation arrested the movements for about forty minutes after the injection of the drug. The saliva was flowing profusely from the action of the drug.

Experiment VI.—Rabbit: Etherized, received .2 gramme morphia subcutaneously. In about half an hour the splanchnics were nearly completely paralyzed.

Experiment VII.—Rabbit: Etherized, received .0008 gramme eserin subcutaneously. In fifteen minutes the splanchnics were still active, although tetanus of the intestine was present.

Experiment VIII.—Rabbit: Etherized, received 1 gtt. of nicotine subcutaneously. In the beginning the splanchnics were active, but finally they failed to respond.

MEDICAL PROGRESS.

TREATMENT OF TUMORS BY ELECTROLYSIS.—NEFTEL has returned to this method of treating malignant tumors, destroying them at a single operation. A platinum anode is plunged perpendicularly into the tumor down to its presumed point of implantation, and from three to five cathodes placed on the periphery of the tumor. The current is then closed and rapidly carried to its greatest power (30 to 60 elements). The position of the cathodes is changed about every five minutes, so as to cover every part of the tumor. The operation lasts about an hour. The tumor becomes livid, gray, and finally black. There is a very slight general, and local reaction. In two or three days the part operated upon becomes cold, and after some discharge finally comes away *en bloc*, leaving a denuded surface which is soon covered by healthy granulations. Neftel has also treated benign tumors by this method, though they do not require such energetic treatment as those of the malignant type. The conclusions which he draws are: 1. Electrolysis is an antiseptic method, and as such may be combined with the ordinary methods of operation. 2. It is preferable to any other method in the treatment of malignant tumors. 3 Malignant tumors should be entirely destroyed by the operation, and at a single séance. In benign tumors it is sufficient to establish a retrograde metamorphosis.—*Virchow's Archiv*, Bd. lxxxvi. Hft. 1.—*Bull. Gén. de Thérap.*, July 30, 1883.

Rupture of the Small Intestine: Resection.—At the meeting of the Société de Chirurgie on Aug. 1st, M. Berger made a report on the cases previously reported by Dr. Bouilly. The patient, a strong young man, was kicked by a horse just above the umbilicus, and immediately felt a very violent pain in the abdomen. Some hours later he was admitted to the hospital with all the signs of peritonitis. Rupture of the intestine was diagnosticated, and laparotomy was performed. Two ruptures were found at a short distance from each other, with violent congestion of the intestine and escape of the contents into the peritoneal cavity. M. Bouilly, in view of the double rupture, resected the injured portion, and removed an injured portion of the mesentery at the same time. A double series of sutures was put in, the peritoneal cavity carefully dressed, and the abdomen closed. Opium was administered to prevent peristaltic action, and a little champagne and rum given as a stimulant. Although the patient felt better after the operation, the peritonitis, though evidently decreasing, continued. On the second and third days the change for the better was still more marked, the pulse being sensibly stronger. On the third day the bowels acted naturally, but at the same time the sutures ruptured and fecal matter escaped through the abdominal wall. In spite of this accident, the patient did very well until the eighth day; at this time M. Bouilly made an exploration of the wound with one finger. A few hours later, violent pains came on, with vomiting, and the patient succumbed in twenty-four hours.

At the *autopsy* the sutures were found to have given away, but it was evident that the sutured ends of the intestine had been held together by plastic material thrown out by the local peritonitis; and it is probable that the exploration had ruptured this adhesion, causing fecal extravasation and general peritonitis.—*L'Union Méd.*, August 14, 1883.

Chronic Intestinal Catarrh.—Prof. Nothnagel, at the meeting of the k. k. Ærztlicher Gesellschaft zu Wien., on May 18th, spoke on the subject of chronic intestinal catarrh, which, he said, has been little mentioned in text-books. There is also no explanation given, in physiological text-books, of the fact that healthy individuals have generally only one stool in the twenty-four hours; and Nothnagel thinks that no explanation can be given, but that it is one of those arrangements, depending partly on the anatomical relations of the parts, and partly on innervation, for which we cannot account. Chronic intestinal catarrh may be considered to be present when mucus appears in the motions, although the absence of mucus must not be regarded as conclusive evidence against the existence of catarrh.

Nothnagel divides the cases of chronic intestinal catarrh into four classes: 1. Those patients who have a stool every second or third day, often produced artificially; this is the type of primary chronic catarrh of the large intestine, and depends, according to Nothnagel, on diminished anatomical activity of the ganglion-cells: 2. Cases where a stool is passed daily, but each time thin, pulpy, and mixed with mucus: 3. Cases with irregularity in the state of the bowels, sometimes constipation, sometimes diarrhœa, and sometimes an alternation between the two; the diminished activity of the nerve-cells explains the constipation, and the irritation of the feces causes eventually the diarrhœa, which may also be excited by a very small error in diet. 4. Cases with continued diarrhœa. Here, however, chronic ulceration of the bowels must be distinguished from catarrh. Where diarrhœa is present without ulceration of the large intestine, Nothnagel has always found an affection of the small intestine as well. When the food does not undergo its normal changes in the small intestine, it acts as an irritant on the mucous membrane of the colon, and causes the diarrhœa. Some patients have a stool after each meal, some after a mid-day meal only, and some after an evening meal only. Nothnagel would explain this by referring it to nervous influence.—*London Med. Record*, July 15, 1883.

Decoction of Lemons in Malarial Fever.—Dr. Maglieri has recently used a decoction of lemons in cases of intermittent fever, with much satisfaction. It was first used in three bad cases, being administered about four hours before the expected paroxysm. The results were, absence of the paroxysm in one case, only a slight paroxysm in the second, and sensible amelioration of all the symptoms in the third, a case in which quinine had failed to produce good results. A fourth case is also reported in which large doses of quinine had no effect, but in which decoction of lemons was successful. Maglieri concludes that: 1. Decoction of lemons employed in malarial affections gives results equal, and often superior to those of quinine. 2. It is not only efficacious in the same cases in which quinine gives good results, but in cases in which the latter has no effect. 3. It is not less efficacious in chronic than in acute malarial affecions. 4. It has none of the inconveniences of quinine (irritating action on the mucous membranes and roaring in the ears). 5. It may be given even during a catarrhal state of the digestive tract. The decoction is prepared by cutting a fresh lemon into small pieces; three cups of water are then boiled down to one cup, the pieces of lemon are put in and thoroughly pressed. It may be given when cold.—*Bull. Gén. de Thérap.*, July 30, 1883.

Physiological Properties of Doundaké and Doundakine.—The doundaké is a shrub of the rubiaceæ family, and is found on the western coast of Africa. The bark, employed by the natives as a febrifuge, has a very bitter taste. MM. Bochefontaine, Féris, and Marcus have isolated an organic base from the bark—a yellowish powder, formed of microscopic rhombohedral crystals. This powder is bitter, soluble in water and alcohol, and of an alkaline reaction. In Winkler's fluid it precipitates phosphotungstic and phosphomolybdic acids. The experimenters have given it the name "doundakine." Its action on the frog is as follows: The hypodermatic injection of gr. ⅛ of doundakine, representing grs. xxx of the bark, produces death in thirty-six minutes. The physiological effects of the bark and doundakine are identical, and may be stated as follows: In the frog, in from two to five minutes, there are noticed a little feebleness and diminution of spontaneous and reflex movements, the frog being incapable of assuming a normal position. Placed in any particular position, he remains so without attempting to change it. Muscular contractility and nervous excitability were maintained, and the heart's action was not sensibly modified. This first period is followed by a second, in which the respiratory movements are irregular and then intermittent, become slow, and are finally arrested, while the heart-beat is regular, though somewhat slower. The reflex movements are gradually abolished.

The same results are obtained when the experiment is made on a frog from which the brain has been removed. But if the cord is cut at the level of the calamus, the frog dies without presenting the above phenomena. The striking fact of the action of the drug is the progressive slowing and arrest of respiration, which takes place while the heart's beat is perfectly regular. The experimenters conclude that doundakine is a toxic agent, acting more particularly on the medulla and cerebellum, and inducing a cataleptic state.—*Gaz. Hebdom.*, Aug. 3, 1883.

Resorcin as a Local Application.—Dr. Bombin has made extensive trials of resorcin, oxyphenol or diatomic carbolic acid ($C_{12}H_6O_4$), as a local application. He uses the drug in the form of alcoholic solutions of different proportions. The first, of equal parts of resorcin and alcohol, has a distinctly caustic action; the second, of one part of the acid to ten of alcohol, and the third of one to twenty, are stimulant and antiseptic. A one per cent. solution is found to perfectly prevent decomposition. In obstinate syphilitic ulceration, Dr. Bombin first cauterizes the surface of the sore with the 100 per cent. solution, and then applies the 10 per cent. solution night and morning till the eschars are separated, and afterwards the 5 per cent. one till cicatrization is complete. He speaks most highly of his success in cases which had been before very intractable. As a local application, he has had very good results in orchitis and epididymitis with a 6 per cent. solution, and uses a 1.5 or 2 per cent. solution with good effect to wash out the bladder, but he considers that it acts in the latter cases simply as a local disinfectant. Moreover, he has not found that, taken internally, it has any curative action in such cases, as has been stated, and similar indecisive results followed its internal administration in cases of strumous glandular affections. In epithelioma of the cervix uteri, its local action does not seem to differ at all from that of carbolic acid; taken internally in large doses, the drug appeared to exercise a certain arresting influence on the spread of the disease, and there was some attempt at cicatrization. On the whole, it is plain that, in Dr. Bombin's opinion, resorcin is a very valuable local application for chronic tertiary ulcerations, exerting on them a distinct curative action, but that the value of the drug when taken internally is doubtful, and that, as a local application, in most cases it is not superior to carbolic acid as a disinfectant, save that it has less smell, and is more soluble in water, ether, and alcohol.—*London Med. Record*, July 15, 1883.

Eucalyptus in Pulmonary Gangrene.—Dr. Bonamy, of Nantes, reports an interesting case of pulmonary gangrene in a patient, æt. 50, who came into the hospital on Oct. 15, 1882. There were fever and dyspnœa, mucous râles in both lungs, but especially in the left; feeble pulse, and the well-known gangrenous odor, so intense that the patient had to be placed in a separate room. The sputum was composed of blackish nodules. There was a great deal of cough which increased the intensely disagreeable odor of the breath. After trying a carbolic acid mixture for two days and finding no improvement in any symptom, Dr. Bonamy prescribed the following: Alcoholate of eucalyptus, ♏xxx; sweetened water, f℥iij; syrup of poppies, fʒv; quinine being given at the same time. On Nov. 6th, twenty-two days after the patient was first seen, the bad symptoms had almost entirely disappeared.—*Bull. Gén. de Thérap.*, July 30, 1883.

Ligation of the Common Iliac.—At the Twelfth Congress of the German Surgical Association, Kümmel, of Hamburg, reported the case of a young man, æt. 21, upon whom the operation for double extirpation of bubo had been performed. Though antiseptic precautions were used, a diphtheritic process was set up in the wound in the left side, and four days after the operation the external iliac was ligated on account of hemorrhage from the central end of the femoral. Secondary hemorrhage again occurred, and the common iliac was ligated. Ten days afterwards, profuse secondary hemorrhage occurred from the peripheral end of the femoral on account of gangrene, and amputation was performed. The patient finally recovered. Ligation of the common iliac has been performed fifty-five times, the great majority of the operations having been performed by English and American surgeons. It has only been done three times in Germany, all fatal. Of the fifty-five cases, forty-one were fatal, from collapse, gangrene of the extremities, and septic infection from the wound.—Beilage zum *Centralbl. f. Chirur.*, No. 23.

Compound Comminuted Fracture of the Skull, with Wound of the Superior Longitudinal Sinus; Lateral Suture of Vein-wound.—Dr. Charles T. Parkes, of Chicago, reports the following interesting case: B. B., æt. 27, laborer, was admitted to the Cook County Hospital, June 20th, at 4.50 p.m., suffering from a compound comminuted and depressed fracture of the skull. Patient has always enjoyed good health; no hereditary taint, nor venereal accidents. Has been a moderate drinker, but was not under the influence of liquor at the time of the accident.

While working on a building several bricks fell from the top of a wall, one of which struck him on the head, prostrating him, but not so that he lost consciousness. The hemorrhage was then quite profuse; a few rude attempts were made to control it until he was conveyed to the County Hospital.

On admission his general condition was fair; hemorrhage had nearly ceased, looked otherwise in good health.

On examination a lacerated wound of scalp was found about two inches in length, of general triangular form, over right parietal bone, above and posterior to the parietal eminence, extending to the median line; also a depressed fracture in same locality, one and a half inch in diameter, oval in form, was made out. There were sensations of numbness and loss of motion in both upper and lower extremity—left side. Dr. Parkes had the patient immediately anæsthetized, and after enlarging the external wound slightly, four fragments of the external table of the skull were removed. This operation was followed by such terrific hemorrhage that no further attempt was made to remove other fragments. The hemorrhage coming from the superior longitudinal sinus was controlled by packing the wound with gauze, and applying a compress. Several small vessels of the scalp were also twisted.

On June 21st, Dr. Parkes removed compress and gauze, and extracted three fragments of the internal table and one of the external table. Hemorrhage again occurred from a perforation in superior longitudinal sinus about size of a coffee-grain. This was closed by three catgut sutures, perfectly controlling the hemorrhage. Slight compress of gauze again applied; scalp wound partly closed by one silk ligature; the whole retained by bandage. The fragments taken from inner table of skull were four in number. The fragment from the external table was the fifth fragment from that table.

On July 20th the pulse and temperature were normal, the paralysis was gone, there was no pain, no inconvenience whatever; says he is all right; only slight loss of motion remaining in toes of left foot; dressed the head; from right and lower margin removed a piece of bone, which was found protruding and loose; from this time on several small pieces were removed, evidently fragments which had become necrotic on the edges.

On September 8th, there was no suppuration, motion and sensation had returned almost completely in the affected extremities, and the patient was discharged well and strong.—*Annals of Anat. and Surg.*, September, 1883.

Ectopia of the Heart.—Prof. Tarnier, at the meeting of the Académie de Médecine of July 31st, introduced to its notice a highly interesting case of ectopia of the heart. The subject of it is a woman at the end of her pregnancy with her second child, no inconvenience having attended her first delivery. The sternum is bifid at its lower portion, so that the heart lies just below the skin. The ventricles can be taken hold of by the hand, but in order to feel the pulsation of the auricles the fingers must be passed into the upper part of the sternal cleft. The patient is also the subject of an umbilical hernia, and the displaced heart seems to have some immediate relations with this hernia. It would be difficult to appreciate the exact relations of the displaced organ. Is the pericardium intact? Is the heart free in the abdominal cavity? It is absolutely impossible to pronounce an opinion on this point. All that can be affirmed is, that the diaphragm is perforated, and that it is through this perforation the heart has passed, and become placed under the skin, accompanied or not with its proper serous membrane. After the woman has been delivered at the Maternité, where she is at present, the phenomena will be investigated by MM. Marey and Franck.

Prof. Marey stated that he and M. Franck had already taken some tracings. "This is," he observed, "one of the most interesting of cases, for it will allow, I have no doubt, of our verifying on the human subject the results obtained by experiments made on the heart in animals, such as the synchronism of the ventricles, etc. In this way, and without insisting at present more on the subject, the exploration of the heart of this woman will allow of our exhibiting the illusion which has given rise to the theory of Beau for the explanation of the pulsations of the heart. Beau explained the beating of the heart by cardiac dilatation under the influence of the afflux of blood at the moment of the ventricular diastole. This opinion appeared logical, for it is rational to admit that the impulse is produced at the instant when the organ increases in volume, and not when it contracts upon itself. But this explanation, however logical it may appear, is not the true one, and if any doubt exists about it an examination of this patient must carry conviction. If, in place of looking at her heart, we seize hold of it with the fingers, we prove in the most distinct manner that it is not when the heart is largest that the impulse is produced, but really when it is hardest. If the Academy will appoint a committee in order to examine this woman in relation to cardiac physiology, and it does me the honor of placing me on it, we shall be able after her delivery to undertake a series of researches for the elucidation of these various points. Cases of this kind are, in fact, extremely rare in the adult, and I have only been informed of one which existed at Ribeauvillers, in Alsace." A committee, consisting of Professors Vulpian, Sappey, and Marey, was appointed.—*Med. Times and Gazette*, August 18, 1883.

Diagnostic Value of Uterine Hemorrhage after the Menopause.—During the course of a late clinical lecture on malignant disease of the cervix uteri, Dr. T. Gaillard Thomas stated, as an axiom in gynecology, that if a woman who has normally ceased to menstruate begins to have uterine hemorrhage, always suspect carcinoma. Not infrequently you will see in the medical journals the reports of cases where women who have passed the change of life have begun to menstruate regularly again; but such accounts are altogether deceptive, and, if these cases could be followed out, it would be found, with scarcely a single exception, that the uterine flow was merely the indication of the presence of malignant disease. In other words, there is absolutely no such thing as a return of the menses when a woman has once reached the normal menopause. Not long since a patient of mine in the Woman's Hospital, who is sixty years of age, began to have a flowing from the uterus, and, as there was no indication of any external disease, I applied the curette to the endometrium and drew out some pulpy masses, which I sent to a well-known microscopist for examination. The report that I got from him was that the growth was not malignant in any respect, but was simply a form of polypus. I am perfectly sure, however, that the microscopist is wrong, and for this reason: in the uterus of a woman of sixty, polypi never develop. The organ at that age is completely atrophied. Sometimes in women who have passed the menopause you will find uterine tumors which have all the appearance of fibroids. They are not by any means fibroids, however, but sarcomata.—*New York Med. Journal*, September 1, 1883.

Synovitis of the Wrist with Rice-like Bodies.—Incision in these cases has come again into favor as one of the consequences of antiseptic surgery. MM. Verneuil, Nicaise, and Notta have communicated to the Société de Chirurgie several remarkable examples of its successful employment; and M. Lafosse has recently published a *thèse* in which the whole subject is reviewed. He concludes that medical means, such as blistering, revulsives, etc., have no effect in these cases. Compression by bandages steeped in alcohol or various stimulant liquids are sometimes useful, but they only act by repelling the riziform bodies into the neighboring tendinous sheaths. Injections of tincture of iodine give better results, but they are only applicable to unilocular cysts. Incision and drainage, which formerly were followed by severe accidents, such as purulent sinuses, phlegmon, and purulent infection, are now attended by the best results when performed under the strict antiseptic method. Cures by the first intention, although possible, are quite exceptional.—*Med. Times and Gazette*, Aug. 18, 1883, from *Journ. de Thérap.*, July 25.

Biliary Atrophy and Hypertrophic Cirrhosis of the Liver.—Maffucci, convinced that, between hepatic sclerosis due to retention of bile and that due to simple inflammation of the biliary passages of the great and small interlobular branches, there are grave etiological and anatomical differences, undertook a series of experiments and anatomical observations, which bring him to the following conclusions: 1. Cirrhosis from biliary stasis has altogether a different origin and signification from hypertrophic cirrhosis with jaundice. 2. In cirrhosis from biliary stasis, clinical as well as experimental, a destruction of hepatic parenchyma precedes, which is repaired by new formation of connective tissue and biliary ducts, the epithelium of which starts from preëxisting tubes. 3. In hypertrophic cirrhosis the acini remain intact, their trabeculæ are transformed into true embryonic tubes, and the connective tissue accompanies and follows the different phases of the same hepatic parenchyma. 4. Very similar to hypertrophic cirrhosis is the experimental process obtained without retention of bile. 5. In cirrhosis from biliary stasis, as well as in hypertrophic cirrhosis, there is an angiocolitis; in the first it is owing to the retention of the bile; in the second it depends on various causes, all of which are not yet known. 6. In hypertrophic cirrhosis, the irritation of the hepatic parenchyma may arise from the large biliary ducts, as happens in experiments, or from causes that acts directly on the parenchyma, as in clinical cases. 7. It is not the new formation of connective tissue which surrounds and invades the acini, nor the new formation of bile-ducts from those preceding, which constitutes the chief character of hypertrophic cirrhosis.—*London Med. Record*, August, 1883.

Salicylate of Soda in Diarrhœa.—Dr. Calleza terminates an article on the pathology of diarrhœas, their classification, and the use of salicylate of soda in fermentative diarrhœa, with the following conclusions:

1. The products of the putrefaction of the materials which pass through the digestive canal cause not only a great number of diarrhœal states evidently idiopathic, but also many cases of secondary diarrhœa, in which a preëxisting disease has engendered a disposition to putrefaction, which is developed under the least abnormal influences.

2. Salicylate of soda is the most efficacious agent for the prevention of putrefactive fermentation in the intestinal canal, without causing troubles of the normal metamorphosis of digestion. It should always be employed when there is a great fetor of the stools, especially if this characteristic has been noticed at the commencement of the trouble.

3. An amount varying from grs. xxx to xlv *per diem*, given in two or three doses, is sufficient to cause rapid cure of putrefactive diarrhœa, when it is idiopathic in the whole sense of the word.

4. In those cases which are really secondary (and they form a very small number), salicylate of soda may also be used with advantage.

5. In syphilitic and phthisical diarrhœas, and in those which accompany visceral abscesses—and especially abscesses of the liver—and dysentery, salicylate of soda has given the best results.—*L'Union Méd. du Canada*, July, 1883.

Papilloma of the Bladder.—A case is described by Rauschenbusch of a growth occurring in a man æt. 43, which was removed by operation. The patient had been suffering from bleeding from the urethra and cystitis for about a year, and when in the hospital he often passed bits of a villous tumor with his water, the dendritic character of which could be easily determined by floating them out in water. The tumor could be felt at the base of the bladder, by introducing the hand into the rectum whilst a catheter was in the bladder. Median lithotomy was performed, and the tumor, which was attached by a long stalk, was seized and twisted off, so as to avoid all danger of hemorrhage. Three or four weeks later the patient was free from all symptoms, and the wound healed. A year later there had been no return. The author draws attention to the fact that only seven cases of such operations are recorded, and in only five cases were they attended by success. It appears, too, that the favorite seat of these tumors is on the trigone, and near the orifices of the ureters, very rarely if ever at the top or sides of the bladder.—*Practitioner*, August, 1883.

Treatment of Varicocele by Intervenous Injections of Alcohol.—Kranzfeld describes (*Vrach. Vedom.*, No. 540, 1882) a simple and easy method of treating varicocele, which had been successfully practised in seven patients by Dr. G. T. Dukhnovsky, of the Odessa Military Hospital. The method consists in injections of 85 to 90 per cent. alcohol into the subcutaneous cellular tissue surrounding the spermatic veins. The needle of a Pravaz's syringe is introduced under the skin at any point facing the dilated veins, and is brought, with the help of the operator's left hand, as nearly as possible to the diseased vessels; then the syringe is slowly emptied. The injection causes only moderate burning pain, lasting from half an hour to three hours. On the next day after the operation there appears a considerable, but almost painless, swelling of the parts, which is at first soft, then becomes more tense. The injections are repeated at three or four days' intervals, from three to ten times, according to the demands of the case. Finally, the spermatic veins are transformed into thin hard cords. In all the seven patients of Dr. Dukhnovsky cure was complete (at least the patients remain quite well as yet). The same method proved equally efficacious in two cases of dilated veins of the leg.—*London Med. Record*, August, 1883.

Capillary Pulse.—In normal physiological existence, the pulse-waves become so toned down by the elastic property of the arterial walls that no pulse can be said to exist in the capillaries. Under certain circumstances the pulse-wave is carried over to the capillary vessels and may be there demonstrated. Quincke published a paper on the subject in 1868 in the *Berliner klin. Wochenschrift*, No. 34. According to him, the capillary pulse, characterized by alternating pallor and redness of the tissues isochronous with the systole and diastole of the heart's action, is specially perceptible in the matrices beneath the nails. The phenomenon may be seen sometimes in the healthy body, in those suffering from anæmia, and especially in individuals the subjects of aortic regurgitation. Quincke further observed the capillary pulse in the capillaries of the fundus oculi of two patients under treatment for valvular insufficiency of the aorta. Writing in *La France Médicale*, No. 15, M. Albert Ruault has again drawn attention to the phenomenon. He recommends the production of a vaso-motor disturbance by drawing the finger-nail smartly across the skin of the forehead and studying any variations which may present themselves. A sensitive area, so to speak, is thus produced where the capillary pulse may be seen in those in whom it happens to exist. Ruault has observed the condition in various pathological states where the coexistence of excessive cardiac impulse and general arterial narrowing was noted.—*Lancet*, Aug. 18, 1883.

Primary Tubercular Arthritis.—Dr. F. Arnaud, in a recent paper on this subject, in which he reports two cases, draws the following conclusions:

1. Tuberculosis of the synovial membranes is primary and independent of osseous lesions, or secondary (osteo-arthritis) and consecutive to the development of tubercles of the epiphyses.

2. Primitive tuberculization, with which we are now concerned, is manifested in the synovial membrane under the two anatomical forms of grayish granulations, and microscopic elementary tubercle. This elementary tubercle always accompanies the granulation, but it may exist alone, independent of any tubercular lesion visible to the eye.

3. Synovial tubercles have been found and studied in fungous tissue, but may be observed in the absence of any fungous alterations, and also in the fistulous tracts in the walls of periarticular abscesses, especially where the new growth has developed by a true inoculation.

4. The tuberculous nature of chronic arthritis may easily pass unperceived unless microscopic examination be made. It is important in all cases of arthritis, with or without osseous lesions, to make a complete anatomical and histological examination of the synovial membrane and of the periarticular tissues.

5. We believe that ultimate researches will demonstrate the tuberculous nature of a certain number of white tumors of the soft parts, of fungous or non-fungous chronic arthritis, hitherto attributed to scrofula, rheumatism, and unknown causes.—*Revue de Chirurgie*, July, 1883.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,
Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia, Pa.

SATURDAY, SEPTEMBER 8, 1883.

SANITARY SINS AT RYE BEACH.

There may be a question whether the sins of the moral life of man are atoned for here, or in the world to come. But as regards sanitary sins there can be no doubt: the punishment follows quickly on the commission of the offence. The offender is caught *in flagrante delictu*, and he cannot plead ignorance, or lack of intent, in stay of execution, but is summarily punished to the full extent of the law.

In the recent outbreak of fever at Rye Beach, New Hampshire, we have an illustration of this great truth as complete in all the details, as it is exempt from the usual fallacies. The great facts true of Rye, are equally true of many of the well-known resorts on the Atlantic coast. It is in the highest degree important to ascertain with precision the source and character of the sanitary evils which beset the summer visitor. Nothing less than the clearest and entirely unquestionable exposition of the sanitary evils of seaside and other resorts will suffice, for the proprietors of these places do not exercise their functions with strictly humanitarian considerations. The problem set themselves is, how to obtain the maximum of profit with the minimum of expenditure. Sanitary works are expensive and fruitless of profit. They can realize the duty of providing a proper water supply and suitable drainage, only when the occurrence of epidemics or filth maladies proclaim the unsanitary condition of their establishments, alarm the summer visitor, and stop the inflow of the "almighty dollar." Such a disaster threatens Rye and its annexes. The experience of the present season is ominous. A well-known citizen of Philadelphia — as all the world has been informed—fell a victim to a most obvious sanitary evil created on his own grounds, and others have sickened and died from the same causes at other places in Rye. At numerous other resorts along the Atlantic coast, similar conditions exist; at some of them every year the evil results are manifest, but gradually in all the preparations are making for future epidemics or for the occurrence of filth diseases in an endemic form. We cannot, therefore, be charged with a special animosity against Rye. This beautiful retreat happens for the moment to be an object of attention and solicitude, because of the sad experiences which have startled the public. Others await their turn.

Having had the opportunity for a personal study of the local conditions, and of the resulting diseases, we are able to offer to our readers exact observations, instead of vague impressions. The subject is naturally divisible into two topics: the etiological factors; the pathogeny and clinical history of the disease. We do not exaggerate in any small degree when we affirm that the developments at Rye afford a strong illumination of disputed etiological and pathological questions. Persons in good health going to Rye, drink water plainly polluted, and suffer from a peculiar and distinctive type of fever. Beside the present, there are past experiences of the same character. In all instances, there are peculiarly favorable conditions for ascertaining the cause and for tracing out the results. Every hour of the daily life, and every influence which can affect the individual, can be accounted for.

First, then, we purpose to examine the etiological factors. The summer boarding-houses grouped about Rye Beach, Little Boar's Head, and Hampton are either the houses, as originally built, of the farmers occupying this shore, enlarged to accommodate the guests, or they are newly constructed on the same plan, of the required size, with modifications imposed by the demands of summer visitors. There are also some cottages and a fine new hotel in the Queen Anne style. Some of the last-mentioned structures are provided with drainage into the ocean, just in front of the main building, but the most of them have only ordinary privies, without vaults, or at most only superficial pits. At the beautiful and artistic new cottage just erected, where the cases of fever were most numerous, the sanitary arrangements are entirely modern. The house excreta are discharged into a vault some twenty feet distant. The well furnishing the water supply and the vault are not more than twenty feet apart, and both are thirty feet in depth.

Soon after the use of the water began in June last, it was observed to have a peculiar odor and taste, and presently assumed a milky appearance.

The cases of illness soon began to occur. The peculiar character of the fever which had its origin in these conditions will be set forth in a subsequent issue. The water was immediately suspected, and indeed no fine chemical analysis was necessary to determine the fact of its contamination; the senses of all who approached a vessel containing it were assailed by the pronounced fecal odor. There are odors and odors. The smell emitted by the water of this well smacked of age, and was rather that of an old privy vault than recent feces. The careful investigation then made disclosed the following condition: When the vault had been thoroughly emptied and cleaned, and the house-drainage conducted by pipes into the ocean, the well was pumped out, and the source of contamination looked for. Then it was discovered that a fecal mixture, milky in appearance and consistence, and powerfully offensive, oozed up in quantity from the bottom of the well.

It seems hardly credible that such a material, and in such quantity, should pour into the water-well from a newly-built and very recently occupied vault. A little investigation disclosed a very unexpected source of contamination, which may be responsible for the evil in the present instance. The neighboring property to the cottage above referred to is within a distance of thirty feet, but the well of the former is supplied by a spring nearer the surface of the ground, and is twenty feet in depth. The whole drainage from this cottage is conducted to a manure heap under the stable, and lies on the surface of the ground. Occupied for eight years, the drainage from this cottage has been slowly percolating through the soil during this period, for an inspection of the surrounding vegetation showed that there had been no overflow from the dung-heap. In fact, all the liquid material had disappeared in the ground—in a direction, which seems to be now explained. In digging a new well to the depth of thirty feet, it is probable that communication has been made with a reservoir in which this foulness has been accumulating for several years. An examination of the water of the new well, made several weeks after the adjacent new cesspool had been carefully cleaned, showed that it had lost nothing of its offensive character. It would appear conclusive that the supply of fecal matter from the new and tightly built cesspool, was hardly adequate to keep up the water contamination, and that the real source of the mischief is to be found in the neighboring premises.

In this unfortunate example of bad sanitation, we have an illustration of some sanitary sins now being committed at Rye. Cottages, large boarding-houses, and summer hotels are supplied with water by superficial wells, and common privies and privy vaults exist alongside. That diffusion of such excrementitious matter into wells and tightly-closed cisterns will take place, is a physical fact capable of ready explanation by the laws of adhesion and diffusion, and is attested by the uniform experience of civilized communities. That drinking-water under such conditions may be poisoned, and yet present no evidence of contamination that may be recognized by the senses, is also a fact; but usually on proper examination the presence of nitrates—products of the oxidation of organic matter, and of the various excreta comprehended in the term sewage—can readily enough be ascertained. There is, however, to be drawn an important distinction between sewage itself and certain accidental constituents, as disease germs. Sewage is capable of slowly poisoning the solids and fluids of the body; but for the production of specific diseases, special germs are necessary, for we are not more able in pathology than in organized nature to admit the doctrine of spontaneous generation.

DANGERS OF CANNED FOOD.

Attention is called to the paper by Dr. W. E. Magruder, printed in another part of this journal, giving an account of a case of well-marked lead-poisoning from the use of corn put up in tin cans, and suggesting that this cause of disease may be often overlooked if its possibility is not borne in mind.

When we consider the great extent of the business of canning food, and the large quantities of fruits, vegetables, and meats preserved in this manner which have been consumed all over the world, and especially in this country, during the last twenty-five years; and, on the other hand, remember that in all that time not more than half a dozen cases of disease supposed to be due to metallic poisoning from this source have been reported, it is evident that the danger of such an occurrence must be very small.

It is very fortunate that this is the case, for not only are the commercial interests involved extensive and important, but it touches the food supply of a large and increasing number of people, to whom the use of these canned provisions has become almost a necessity, instead of a luxury, as it was at first.

Several investigations have been made by chemists within the last few years as to the presence of metallic salts in the contents of tin cans, and from these it would seem that most canned fruits contain small amounts of tin. When tin is present in the proportion of half a grain to a pound of canned fruit it can be detected by the taste, but there is no evidence that this quantity of tin is injurious to health. In comparatively large quantities some salts of tin are irritant poisons, but the effect of small quantities does not appear to be cumulative.

The experiments of Mr. Francis P. Hall, reported in the *American Chemical Journal* for March, 1883, showed that in the absence of air, as in sealed cans, vegetable acids have very little effect on tin, or on an alloy of lead and tin. When, however, such acids are placed in ordinary tin cans which are left open, the tinning is rapidly dissolved.

The principal danger of metallic poisoning from canned goods is due to lead. This may be derived either from the tin-plate or from the solder. There appears to be much variation in the amount of lead contained in tin-plate. Traces of lead sufficient to produce the color-test exist in almost all specimens, while the lower grades of roofing or terne-plate contain a quantity sufficient to make cans dangerous which are manufactured from them.

Mr. Hall did not find any cans made from such plate, but there is little doubt that such cans are in the market. It is to the interest of those engaged largely in the canning business to secure a good reputation for their goods, and it is probable that, as a rule, they use only cans made of a good quality of bright plate. The cans made of inferior plate would be more apt to be made for sale to farmers, etc., for domestic use. The danger of contamination from the lead contained in the solder depends upon the way in which the can is made. In a machine-made can by a good and careful workman, the amount of surface of solder exposed to the action of the contents of the can is very small, little more, in fact, than the area of the vent-hole, which must always be filled by solder. In a hand-made can by a careless workman, a square inch or more of solder surface may be present on the inside of the can. Drops of solder may also fall into the can in the process of sealing, and most of our readers must have seen such fragments of solder. If they have not, their cooks have.

It seems probable that time is an important element in the action of the contents of the can upon it, and that cans two or three years old will be much more apt to be eroded than those which have only been put up a few months. The suggestion of the editor of the *Sanitary Engineer*, that every can should bear the date of the year when it is put up, is therefore a good one.

Special investigation is needed to determine the cause of exceptional cases, such as that reported by Dr. Magruder, but it does not seem as if the explanation in this case would be difficult. A cheap can, made probably of terne-plate, the addition of tartaric acid to the contents—probably unskilled soldering—and a body specially susceptible to the effects of lead make up the factors in the case. The moral of it all, so far as our information extends at present, is included in the following:

1. In purchasing cans to do your own canning, do not take a cheap, dull-looking article.
2. When you add an acid it should be neutralized before the article is placed in the can.
3. When the inner surface of a can, or of its cover, is found, on opening, to be corroded or to present a crystalline structure, the contents of that can should be regarded as suspicious.
4. When a can is opened it should always be emptied at once, and not be set aside half-full.
5. In cases of obscure nervous affections look out for lead-poisoning, and bear in mind the use of canned food as a source of such poisoning.

SUDDEN DEATH FROM GOITRE.

In *Langenbeck's Archiv f. klin. Chirurgie* (Bd. xxix. Heft 1), Seitz has an interesting article on sudden death from paralysis of the vocal chords in goitre, which emphasizes the necessity for great watchfulness, and, if need be, of tracheotomy as a prophylactic measure, if there be even the slightest dyspnœa.

The case which he reports is most striking. A young woman of twenty sought his aid, merely with a view to improvement of her appearance. Later evidence, after death, showed that she had had some dyspnœa and cough, but so slight that she did not even name them. Noticing a somewhat altered voice in coughing, it occurred to him that the recurrent nerve might be affected, and he appointed a visit on the next Sunday for a careful laryngoscopic examination. As Seitz dramatically puts it, "der nächste war ein herrlicher Sonntag—das Fräulein eine Leiche!" At three in the morning following her first visit to him, she suddenly stood by her father's bed, pointed to her throat, and, without uttering a sound, fell dead at his feet! The autopsy showed absolutely nothing anywhere abnormal, save that the left recurrent nerve was larger than the right, and was flatter where it was gripped by the enlarged thyroid (which reached to the spine, and had burrowed between the trachea and œsophagus) than it was below.

Sudden death in goitre may follow from bursting of the cysts (if it be of the cystic variety) into either the trachea or the pharynx, by sudden enlargement of the gland, by apoplexy in the gland, by compression of the trachea, either directly by the enlarged gland or by muscular contraction of the overlying muscles of the neck, or finally either by spasm of the muscles which close the glottis or paralysis of the muscles which open it.

Rose emphatically denies the possibilities of sudden death from paralysis of the vocal chords without spasm of the opponent muscles, and it is at least a question whether, in the case of Seitz, the pressure of the tumor was not enough to irritate rather than to paralyze, for it must be remembered that the filaments to both sets of muscles—the openers and the closers of the glottis—run in the recurrent.

Certain it is that spasm of the closers of the glottis may cause sudden death. We have twice seen it in tetanus, so that we should hereafter regard a single urgent attack of dyspnœa in this disease a sufficient reason for instant tracheotomy; and in whooping-cough it is a well-recognized, though rare, cause of sudden death, as well as in pure spasm of the glottis. As to paralysis of the glottis openers, we are disposed to agree with Seitz that that may also be a cause of sudden death. The dyspnœa that follows even paresis of these muscles is well known, and it is highly improbable that in all the cases of sudden death he quotes, in which the recurrent was involved either by incorporation with the tumor or by pressure from it, the lesion only went so far as to irritate, and not to paralyze. A similar mechanical action, blocking the respiratory passages by the air-current's striking loose and flabby nostrils, is related by Linhart. Chloroform was administered to a young girl with a narrow nose and thin nostrils; alarming asphyxia soon set in, and he found that it was due to the inspiratory currents forcing the flabby nostrils against the septum, thus completely closing the nares.

The results of experiments upon animals are conflicting, as Seitz points out, from differences in the anatomical distribution of the laryngeal nerves in the vagus and recurrent nerves; and in those cases in which the branches to the posterior arytenoid muscles are cut, dyspnœa, stridor, and asphyxia follow. Whatever view be adopted, urgent dyspnœa in goitre raises a question also as to the advisability of extirpation of the gland. If it be undertaken, not only must the danger of hemorrhage be encountered, but it may also be suspected that the recurrent nerves are involved either by pressure or direct incorporation with the tumor, or else that the dyspnœa is the result of pressure upon the trachea. The laryngoscope will here give us the greatest assistance.

Finally, there may be dyspnœa and sudden death with no possible assignable cause. Stahl reports a case of a girl, aged fifteen, who had had goitre since two years of age. Acute enlargement of the tumor produced dyspnœa, for which Langenbeck did tracheotomy. Momentary relief being followed by renewed dyspnœa, he carried a flexible catheter to the bifurcation at the trachea, but on the third day the patient died from exhaustion, and no possible explanation for the dyspnœa could be found.

In the same journal, Wölffler, of Vienna, has an elaborate study of the development and structure of the thyroid, which will well repay perusal.

NEW TESTS FOR SUGAR—DIAZOBENZOL-SULPHURIC ACID.

Still another recent test for sugar is diazobenzol-sulphuric acid, suggested by Pentzold (*Centralbl. f. klin. Med.*, June 20). Five cubic centimetres of strongly alkalized urine, are treated with five cubic centimetres of a freshly prepared solution of this substance (1 to 60). Immediately the urine becomes yellow, and remains so if sugar be absent. But if sugar is present, a darker hue and diminished transparency at once appear, and in from three minutes to a quarter of an hour, the color passes over into a beautiful bluish-red, that of a concentrated solution of fuchsin. The froth, if present, is orange or reddish-brown in color, but upon shaking, the color passes over into the same red which the fluid also exhibits in thin layers. This bluish-red color of the froth, may be considered typical of glucose in diabetic urines. A scarlet-red reaction, on the other hand, indicates the presence of acetone. This passes over into blue-red if sugar is also present, but remains permanent if only acetone is present.

In the urine of two diabetics, from which he had considered that the sugar had been removed by the use of iodoform and bromide of arsenic, Korvels (*ibid.*) claims to have proved its presence by this test, when Heller's (Moore's) and Trommer's tests furnished entirely negative results. He has obtained a like result, also, in the urine of a child with fracture of the base of the skull, where Heller's, Trommer's, Fehling's, and Mulder's tests were all negative. Quantitatively $\frac{3}{10}$ of one per cent. of sugar were found in the urine.

A similar reaction is furnished by burnt catechin in acid solution; also by urine strongly charged with acetone as well as glucose, although preceded, as above stated, by a brick-red to scarlet-red color. Solution of pure acetone, or urine to which acetone has been added, strikes only the scarlet-red reaction, while that of sugar is blue-red.

The inconvenience of freshly preparing the solution is obviated by adding to the alkalized urine as much of the acid in substance as will go on the point of a knife. The reaction follows, but not so quickly, so that for delicate testing it is better to follow Pentzold's directions.

The similarity of this reaction with that of the picric acid must strike any one familiar with both. The reaction is probably identical, as both the picric acid and the benzole compound are petroleum products; and it is now likely that more than one of this series may be used as sugar tests.

ARMY AND NAVY EXAMINING BOARDS.

We every now and then hear of candidates passing fair professional examinations before the Government Medical Examining Boards, who are found deficient in general culture, and an impression has got abroad that these Boards are prone to lay undue stress upon the general literary attainments of the candidates, which in turn has an unfortunate influence upon the course of studies they pursue preparatory to coming up for examination. We have recently heard of a case in point, in which a young man passed an excellent examination in ancient and modern languages, and the subjects of a liberal education, but who failed signally in his professional studies. That such a man has capacity is very evident, and he only requires to apply himself to become as well qualified in professional subjects as he is in those pertaining to a liberal education.

We suggest, therefore, that hereafter in the circular-letter which is furnished to candidates, some notice be taken of this circumstance, and candidates be duly notified that while a fair knowledge of ancient and modern languages, and of mathematics, physics, and other subjects of a good preliminary education is required, it must in no way be considered as a substitute for thorough professional training.

REVIEWS.

Dr. John Brown's Spare Hours.

Rarely have we enjoyed a book more than the third series of Dr. John Brown's *Spare Hours*. Its American title is a rather unhappy translation of the author's *Horæ Subsecivæ*, but the "pith and marrow" is just as good under one name as another. The general popularity of the first two volumes is such that *Rab and his Friends* is now an English classic, and few of our readers, we trust, are not friends of *Marjorie Fleming*, with her "Newgate calendar of all the criminals as ever was hung," or are ignorant of the *Mystery of Black and Tan*, or the splendid description of Chalmers, or the loving tribute to his father.

The present recent volume—and we must add the last we shall ever have from his accomplished pen, now, alas! laid aside for ever—contains mostly purely professional papers, and as such will interest us all as physicians.

Most of us would take exception to the genial doctor's conviction "that a mediciner should be as free to exercise his gifts as an architect or a mole-catcher," but all surely will be with him in his plea "for the cultivation and concentration of the unassisted senses. This phrase is the key-note, indeed, to most of the volume. We are apt, amidst our learning and our scientific observations, to forget that the ear, the eye, and the hand are after all the chief avenues of knowledge, and to neglect their finer cultivation in our eagerness to learn the mysteries of all our "scopes" and our reagents. We need the *experientia* as well as the *experimenta*. And it comes with peculiar force from one who is such an exuberant classical scholar that his Latin and his quotations from the older English classics overflow on almost every page.

The paper on Locke and Sydenham will especially well repay an attentive perusal. It places Locke, as an active practitioner of medicine—a fact not generally known—in his true relation to our profession; while his notice of Sydenham—the "Prince of English physicians," such that Boerhave, whenever he mentioned his name, was wont to take off his hat—gives us more of wit and wisdom, of learning and wise precept, than almost any similar sketch we have ever read.

Another quality that is noticeable throughout the book is Dr. Brown's genuine, unaffected piety. His religious nature, like Sydenham's, is always evident, but never obtrusive. It is more a motive than an emotion, and leads to action rather than to theory or mere contemplative enjoyment. His was preëminently a religious *life*, and his profession gave him many opportunities for its practical manifestation.

He has embalmed the memory of more than one "Gideon Gray" in his delightful pages as examples and incentives to modest, conscientious work in rural seclusion. His paper on Dr. Adams, of Banchory, may well put to shame many a man who has means and opportunities, and encourage "country doctors" to believe that in spite of the lack of both they may acquire a generous education. Beginning when a lad of fifteen with seventeen hours a day on Virgil and Horace, each of which he read six or seven times in succession, Adams next read almost every Greek work excepting those of the ecclesiastical writers. Settling in a secluded village, he spent his days in the arduous and useful life of a country surgeon, having the lives, the births, and the deaths of a wild outlying region on his hands. Yet while faithfully attending to such an exacting practice, fighting for a living, and educating a family, he contrived to become "the most learned of Scottish physicians," translated Paulus Ægineta and Hippocrates for the Sydenham Society, besides numerous classical papers, wrote a series of papers on the construction of the placenta, on uterine hemorrhage, on burns, lupus, dislocations, etc., and amused himself at breakfast by translating an ode of Horace into Greek verse!

But our readers must enjoy the book for themselves. It is replete with good-sense and much learning, dashed with not a little genuine humor, and not spoiled by the occasional Scotticisms amidst a charming English only rivalled by that of our own Holmes.

SOCIETY PROCEEDINGS.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Seventh Annual Meeting, held at Sagamore House, Lake George, August 29, 30, and 31.

(Specially reported for The Medical News.)

Wednesday, August 29th, First Day.

Morning Session.

The meeting was called to order by the President, Dr. R. W. Taylor, of New York, who made a few remarks and called for the reading of the papers.

Dr. Piffard, of New York, read a paper on

THE TREATMENT OF ACNE.

Etiology is the main feature to be looked into. The chief physical factors in the production of the disease are already known. One of the commonest in women is disorder of the uterine functions. There are incurable cases of uterine disease accompanied by acne, in which the skin affection is incurable; it is no use attempting treatment. In acute acne, one of the best remedies for internal use is calx sulphurata in minute doses. Bromide of arsenic is also a valuable remedy in the dose of $\frac{1}{100}$ to $\frac{1}{50}$ grain, made into a one per cent. solution in alcohol; one to two minims may be administered in a wineglassful of water. If the stomach becomes upset, its use must be suspended. The sulphide of calcium is most useful in lymphatic subjects, while the bromide of arsenic is suited to acute cases. Locally, some cases do best under early puncture of the lesions followed by the employment of *warm* water, while in other cases simple applications of *hot* water are most beneficial. Sometimes a weak belladonna ointment may be applied at night, or a stramonium ointment, the latter to be made from a fluid extract prepared from freshly gathered leaves.

In chronic acne, sulphide of calcium (calx sulphurata) is to be pushed, beginning with doses of $\frac{1}{50}$ grain and rising. Bichloride of mercury is sometimes of use internally, even where there is no possible suspicion of syphilis. Ergot, the use of which has been recently advocated by Dr. Denslow, of New York, the writer had found useful in practice, although he did not endorse Denslow's theory of its action. The proper dose he had not decided upon, but the drug is by no means a harmless one. Dr. Denslow used it in doses of 20 to 30 minims of the fluid extract. Ergot may also be used to advantage in acne indurata.

Dr. Atkinson, of Baltimore, said that he had never been able to obtain any benefit from the employment of sulphide of calcium.

Dr. Alexander, of New York, confirmed Dr. Atkinson's statement with regard to sulphide of calcium. As for ergot, he had found that of use in diminishing the redness of the skin, but not in removing the lesions. Other members concurred in these statements.

The President, Dr. Taylor, said that in the treatment of acute acne he was accustomed to rely upon the employment of diuretics, *e. g.*, Rochelle salts with acetate of potassium. In indurated acne he employs puncture, also touches the lesions with a solution of pernitrate of mercury together with the application of hot water. He had recently employed a solution of chrysarobin, thirty grains in an ounce of collodium, as suggested by Dr. Fox, of New York. This does not come off on the clothing, and although it necessitates sequestration during its employment, on account of the discoloration of the face, it gives a good result. Internally, he employs Donovan's solution, pushed to 10 or 12 minim doses. Ergot diminishes the hyperæmia, but does not cure the acne. Dilute ung. hydrarg. sometimes produces an excellent effect.

Dr. Stelwagon, of Philadelphia, said that he had succeeded in getting excellent results from a wash of half a drachm each of sulphate of zinc and sulphuret of potassium dissolved in four ounces of water.

Dr. Graham, of Toronto, read a paper on

GENERAL EXFOLIATIVE DERMATITIS,

which he thought occurred more commonly than the literature of the subject would indicate. The writer went on to describe four cases which had come under his personal observation, and concluded by formulating the conclusion that two varieties of exfoliative dermatitis exist, which should be called (1) Dermatitis exfoliativa rubra. (2) Dermatitis bullosa et exfoliativa. The first would include pityriasis rubra and allied forms; the second pemphigus foliaceus.

Dr. Atkinson thought the term "general exfoliative dermatitis" a good one to describe the disease without involving theories as to its nature. Some cases are in all probability tropho-neuroses, while others are more like eczema.

Dr. Geo. H. Fox, of New York, thought that many cases reported as general exfoliative dermatitis and pityriasis rubra are in reality eczema. He himself had seen but two cases of pityriasis rubra, one under the care of the late Dr. Tilbury Fox, in London, and another which he had reported some years ago in an early number of the *Archives of Dermatology*.

Dr. P. A. Morrow, of New York, agreed with the speakers in regarding the affection under consideration a tropho-neurosis. He had obtained benefit in two cases from the use of arsenic.

Dr. Sherwell, of Brooklyn, thought that the designation employed by the writer, Dr. Graham, would not cover the disease pemphigus foliaceus as described by classical authorities in dermatology. He thought the latter a distinct affection which should preserve its distinctive name.

Dr. Piffard also took ground against the conclusions of the writer, maintaining the individuality of pemphigus foliaceus, pityriasis rubra of Hebra, and general exfoliative dermatitis.

The President, Dr. Taylor, described two interesting cases of exfoliative dermatitis, the first occurring as a result of taking quinine in any form, the other in a patient the subject of venereal disease. The latter in its later and chronic stage resembled ichthyosis in its color and appearance.

Dr. Stelwagon read a paper on

IMPETIGO CONTAGIOSA.

This affection, now admitted as a distinct disease by some German authors and attributed to tricophyton and to pediculosis by others, is scarcely, if at all, mentioned by French dermatologists. English and American authors have described it at various times and all admit its individuality with the exception of Hyde, who regards it as the offspring of vaccinia. The writer had had extensive experience in the study of the disease, and having examined above five hundred specimens, he had failed to find any fungus in the fluid of the vesicles and vesico-pustules such as had been described by Kaposi and Piffard. He had found micrococci in the vesico-pustules of impetigo contagiosa as he had in pustular eczema, but he had not found the so-called characteristic fungus except in a very few cases, and then only in the dried crusts. He considers impetigo contagiosa as an exanthematous auto-inoculable disease, naturally acute, but prolonged by auto-inoculation. The disease is: 1. A separate and distinct affection. 2. Not parasitic. 3. Not related in any way to vaccinia. 4. An acute systemic affection.

Dr. Hardaway, of St. Louis, said he had always considered impetigo contagiosa an independent disease; the eruption is typical, and, more than all, it occurs epidemically. If the disease were related to ringworm, impetigo, or vaccinia, we should find it constantly occurring. In reality, it occurs in epidemics. He himself had not seen a case for five years, although his opportunities for observation had greatly increased in that time.

Dr. Atkinson said that he used to think he had a clear and definite idea of impetigo contagiosa. Of late, however, he had seen so many cases of impetiginous eczema occurring in summer-time and readily inoculable, that he felt much more in doubt in regard to the subject than formerly.

Dr. Rohé, of Baltimore, agreed with the writer and speakers regarding the independent character of the disease. He had never succeeded in finding fungus. He did not believe with Hyde that the disease followed vaccinia.

Dr. Fox said that Willan had many years ago described a pustular eruption which was not eczema and was not dependent upon the soil for its inoculation, which he described as "Porrigo." Later, Naylor described the same disease more fully under the same name. Dr. Tilbury Fox described the affection and its epidemic character at length, but unfortunately had given it a new name. The speaker doubted the correctness of Dr. Stelwagon's proposition that the disease is unconnected with vaccinia. He recalled the case of a surgeon who had contracted a typical impetigo contagiosa lesion on the end of his finger by slightly pricking it with a lancet recently used in vaccination. Although pediculosis might not produce impetigo contagiosa *de novo*, the speaker thought it might act in spreading it. The proposition as to the exanthematic nature of the affection brought forward by the writer was new and important.

DR. PIFFARD thought that impetigo contagiosa could not be recognized in Willan's description. Naylor, however, had certainly described it, and he agreed with the last speaker in thinking it a pity that the name porrigo had not been retained. He had had several series of cases under observation, the first member of which in each group was an individual who had recently been vaccinated. While admitting the various points made by the writer, he was still inclined to hold to the fungus theory. He himself had found a peculiar fungus common to vaccinia and impetigo contagiosa, different from that of Kaposi, and unlike any other fungus. Until this should be found in various crusts of other eruptions, he should hold to the fungus view.

THE PRESIDENT, DR. TAYLOR, said that he was firm in his belief that impetigo contagiosa is a disease *sui generis*. He thought it was not a systemic trouble. One proof of this is that the disease always begins locally, as in the face. In sixty cases coming under his notice in a single epidemic, the affection began on the face or about the finger-nails in every instance, the patient afterwards inoculating himself on the body.

DR. STELWAGON said, in reply to Dr. Piffard, that, in five hundred microscopic examinations, he had only found the fungus described by Dr. Piffard five times, and that described by Kaposi ten times. It was in the crust only in every instance.

DR. HARDAWAY said that, in his experience, impetigo contagiosa was quite unconnected with vaccinia. Being public vaccinator in St. Louis, he had vaccinated many thousand persons, and he had never seen impetigo contagiosa result.

EVENING SESSION.

DR. ATKINSON, of Baltimore, read a paper entitled

A CASE OF MULTIPLE CACHECTIC ULCERATION,

Giving an account of a child two years of age, who after some unimportant preliminary symptoms showed signs of itching about the hands and face followed by vesiculation and ulceration. Later a large superficial ulcer appeared on the cheek, nearly covering it from the mouth to the ear. Other ulcers appeared in various parts of the body, and the patient suffered from diarrhœa with emaciation. The eruption was generally ushered in by itching, so that the child bit and scratched the part before the lesion appeared. This was particularly so in the case of one of the fingers, which ulcerated without any sloughing, the tissues seeming to melt away until the end of the finger was completely gone. In some lesions bloody blebs formed at first. Healing took place, finally, in this case with deep scarring. Ergotism, diabetes, and scurvy, could be excluded. The child was well lodged and fed. In recapitulation we have papulation and vesiculation followed by ulceration going through the skin, muscle, and even bone. There was no gangrene in mass, but rapid molecular disintegration. There was loss of power from debility, but no paralysis. Sensibility to pain was probably blunted. There was no symptom of vaso-motor disturbance. The case probably belonged to that class of affections called by the late Oscar Simon "multiple cachectic gangrene." Tonics are demanded in such cases. The prognosis is good, though deep scarring is caused by the disease.

DR. VAN HARLINGEN, of Philadelphia, mentioned a case of spontaneous gangrene of a probably reflex character, which had come under his notice, where patches at first resembling erythema multiforme had eventuated in deep sloughs. This affection occurred in a man who had recently suffered amputation of one of his limbs, and who died shortly after from septic poisoning.

THE PRESIDENT, DR. TAYLOR, mentioned two cases which he had seen, and which were similar in character to those described by the writer. One occurred in a cachectic infant, where a patch of molecular disintegration with red tumid edges and foul ichorous discharge formed on the back, extending over an area of two and a half by four inches, before healing took place, under general tonic and feeding treatment, with great scarring deformity. The second case was that of a nervous woman of thirty, married and childless, who had never taken ergot. Here bullæ formed on the tip of the nose, followed by deep ulceration and a highly deformed scar. At the same time, the fingers of both hands became blue and cyanosed; the pulps of the finger-tips withered in a sort of dry gangrene, finally leaving the attenuated cicatricial points with little more than the finger-nails, giving a griffin-like, claw-shaped appearance to the fingers.

DR. VAN HARLINGEN read a paper on

EXPERIMENTS IN THE USE OF NAPHTOL,

Describing this derivative from coal-tar, a mulberry-colored crystalline substance first introduced into medical practice by Kaposi, of Vienna, who extolled its virtues in various diseases of the skin. The writer agreed with him in regarding it as a remedy of high value in scabies, less so in psoriasis, and useless or harmful in eczema.

DR. FOX said he had used naphtol quite extensively, though not in all the diseases in which it had been recommended. His chief experience with it had been in eczema, where he had failed to get much benefit. In certain cases of eczema of the scrotum and anus, however, it had seemed to act favorably when other remedies failed, and in eczema of the scalp it had also acted pretty well.

DR. HARDAWAY, of St. Louis, had found naphtol of use in eczema squamosum and fissures of the fingers. In psoriasis he had found it inferior to other remedies.

The PRESIDENT, DR. TAYLOR, had employed naphtol in scabies occurring in private practice, with satisfaction.

DR. FOX read a paper entitled

A TRIP TO TRACADIE,

Giving an account of his experience at the leper settlement, where there are at present segregated twenty-four lepers, thirteen males and eleven females. Three cases did not seem to be those of leprosy. The patients are well taken care of, but do not receive medical treatment of any kind. The writer would not decribe the cases at length, as the whole subject had been gone over by his fellow-member, Dr. Graham, who was preparing an official report for the Canadian government. He would, however, make some remarks on the general theory of the disease. The first impression given at Tracadie is that the disease is hereditary, as the lepers almost all bear a few family names in common. These, however, are found to be the family names of the entire community of Tracadie, where the inhabitants have intermarried for generations. The spread of leprosy in communities where we know about it is too rapid to permit the view that it can only be transmitted by hereditary influence. No physician or nurse attending lepers has ever been known to be attacked by the disease. The writer believed that leprosy is transmitted as syphilis is transmitted, by direct contagion. The ulcerative form is, of course, that which is most likely to be spread. He had observed one case in an old woman where the disease had run a certain course, destroying the fingers of both hands, and had then seemingly disappeared spontaneously. He was hopeful of the future discovery of some means by which leprosy could be cured. Even now much has been done in some cases by the internal administration of large doses of nux vomica with inunctions and dressings of chaulmoogra oil.

Dr. Simmons, formerly of Yokohama, who was present, spoke by invitation. He said that his experience, together with the general belief of the Japanese, was in favor of hereditary transmission. He believed that in many cases those accustomed to observing the disease could distinguish the signs of its approach in the countenance of the person long before any distinct objective symptoms made their appearance.

Dr. Sherwell read a paper entitled

PAGET'S DISEASE, OR MALIGNANT PAPILLARY DERMATITIS.

After calling attention to the fact that he had reported some years ago the first case of this affection, which had been published in this country, the writer went on to describe two cases which had come under his observation, and which had presented certain peculiarities different from those described by Paget as characteristic of the disease as observed by him. The writer's conclusions were as follows:

1. Malignant papillary dermatitis presents the subjective symptoms of burning and itching like ordinary eczema, but to a more marked degree, differing in this respect from carcinoma.
2. The objective symptoms, discharge, crusting, etc., are indistinguishable from those of eczema. The color is perhaps more lurid.
3. The "melting away" of the nipple would perhaps be better described as a gradual obliteration.
4. Retraction of the nipple, if this be present, is not to be distinguished from that observed in ordinary cancer.
5. The malignant papillary character is an important point, instantly resolving doubts as to the presence of the disease in question, or that of eczema.
6. In the cases observed by the writer, the duration of the disease was an important point. In one case it was over twelve years, while in the other it was considerably longer than the period assigned by Paget.

Adjourned.

Thursday, August 30th.

Morning Session.

Dr. Morrow, of New York, read a paper entitled

THE PATHOGENESIS OF DRUG ERUPTIONS.

There appear to be two kinds of influences acting in the production of drug eruptions: 1. Constant and typical influences, such as those which give rise to the blebs of cantharides or the pustules of tartrate of antimony. 2. The far from constant influences which flow rather from morbid aptitude in the individual. The internal administration of certain drugs may in one individual produce one sort of eruption, in another a quite different rash, while a third will remain quite unaffected.

Among the theories which have been brought forward to account for the occurrence of drug eruptions, one regards these as the result of the irritation of the drug in passing through the skin, another to the injurious effect of the elimination in its struggle to get out, while a third looks upon these eruptions as the result of elective affinity on the part of certain drugs for certain glands. Behrend holds a peculiar theory of dynamic action, due to the production of a foreign material in the blood by chemical action on the part of the drug introduced into the blood-current. The theory held by the writer, however, was that of neurotic action.

Dr. Taylor, of New York, read a paper on the

POLYMORPHOUS CHANGES OBSERVED IN THE TUBERCULAR SYPHILIDE.

A man of middle age contracted a chancre in April, 1881. No generalized eruption was observed until August, when he suffered from a papular eruption over the body, with mucous patches of the mouth. Under treatment, these lesions disappeared, and no medicine was taken for a year subsequently. In November last, a second rash of large papules came out over the whole body, but no medicine was taken until April of the present year, when the patient came under Dr. Taylor's observation. He then presented an eruption of scaly, psoriasis-like patches, symmetrically distributed over the whole body and scalp. The patient, who was somewhat emaciated, was put upon good diet, and placed under observation, without the administration of anti-syphilitic medication. The diagnosis would at first have been difficult, owing to the very strong resemblance which the lesions bore to those of psoriasis. Degenerative changes, however, soon manifested themselves. The patches gradually assumed a tubercular form, became hypertrophied, raised above the skin, and presented in some cases the appearance of the colloid lesions of lupus, the scaliness meanwhile decreasing greatly and disappearing. Later, bullæ appeared, chiefly on the scalp. This phase soon passed, and some of the lesions took on a rupia-like aspect, while others ulcerated, and others still simply hypertrophied, instead of breaking down. Certain lesions which hypertrophied, ulcerated in the centre, and became covered with thick, conical, rupia-like crusts, while around the edge the epidermis became markedly proliferated, causing these lesions to closely resemble those described and figured by McCall Anderson under the name of psoriasis rupioides. Gummatous ulceration also took place in this case in certain lesions. At the end of seven weeks, when the various manifestations were at their height, mercuric medication was instituted, and the disease disappeared in a short time.

The paper was accompanied by the exhibition of a number of very finely colored photographs, showing the appearance of the disease in its various stages.

Dr. Hardaway said he had recently reported a case of psoriasis rupioides which agreed with McCall Anderson's description. Here the scales piled up so that the lesions presented the conical oyster-shell-like appearance, with a dirty aspect. On removing these crusts, the smooth, flat, moist, red surface of psoriasis presented its characteristic aspect.

Dr. Sherwell, of Brooklyn, read a paper on

PSEUDO-PSORIASIS OF THE PALM.

The writer expressed the belief that, when an eruption of frank psoriasis occurs upon the palm, there is probably a syphilitic taint. He gave a case of a man suffering with psoriasis in whom syphilis appeared. In the course of this, a scaly eruption appeared upon the palm, which was cured by mercurial treatment.

The discussion upon this paper was adjourned until after the reading of the two following papers:

Dr. Alexander, of New York, read a paper on

PSORIASIS OF THE PALM,

giving the history of four cases of unquestionable psoriasis of the palms in which no syphilitic taint existed. These cases were accompanied by photographs showing the exact appearance of the lesions.

Dr. Hyde, of Chicago, who was prevented by sickness from being present, sent a paper entitled

A STUDY OF THE COINCIDENCE OF SYPHILITIC AND NON-SYPHILITIC AFFECTIONS OF THE SKIN,

which was read by Dr. Wigglesworth.

The writer spoke of the assertion which had been made, that syphilis may be mixed with other diatheses, especially in hereditary cases, so that affections which are part lupus and part syphilis, or part psoriasis and part syphilis, may be produced. He went on to give a description of various affections which are met with concomitantly with syphilis, of which the most important is psoriasis, and added a carefully detailed account of a case of psoriasis which had been for five years under his observation, at the end of which time syphilis supervened. The syphilitic eruption ran its course in the same localities as the psoriasis, the lesions being intermingled, but one being relieved by mercury, leaving the other to be afterwards cured by arsenic. The palms and soles were not invaded by either disease.

Dr. Graham, of Toronto, said that he had seen two undoubted cases of psoriasis of the palm where there was no syphilis.

Dr. Morrow said he had until recently agreed with Dr. Sherwell in the belief that psoriasis does not occur in the palms. He had recently had evidence, however, that psoriasis could occur in the palms as a distinct affection, to be distinguished from the palmar syphiloderm.

The President, Dr. Taylor, said that Dr. Alexander's three cases had been seen by him, and the histories examined into with the utmost care, syphilis being certainly eliminated in each instance. In his experience with psoriasis of the hands, the nails are usually first affected. Usually psoriasis may exist for years on various parts of the body before the palms are attacked. He had observed psoriasis beginning about the nails, and then running up to the palms. The tendency seems to be to attack at first those parts of the body where the epidermis is thin and tender, and the palms, where it is thick and hard, only at a later period.

Dr. Sherwell said that in spite of the evidence brought forward for the opposite view, he was inclined to cling to his idea that palmar psoriasis was in fact syphilis. With regard to the elimination of syphilis by Dr. Taylor's careful examination in Dr. Alexander's cases, he thought it not so easy to prove the absence of syphilis. It is much easier to prove the presence of syphilis in any given case than its absence.

Evening Session.

Dr. R. W. Taylor, of New York, read a paper entitled

PECULIAR APPEARANCE OF THE INITIAL LESION OF SYPHILIS.

He had published some years ago, in the *American Journal of Dermatology and Syphilography*, a case in which he had been able to observe the initial lesion of syphilis from its earliest incipiency. A patient presented himself with a lesion which he had observed himself for the first time a few hours previously, and which was in the form of a minute silvery spot, situated within the meatus on a level with, and not in the least elevated above the surrounding mucous membrane, and showing no fissure or other alteration of the surface. Dr. Taylor had watched this lesion, examining it every day for a week, by which time induration had set in and over an area the size of a small pea; the epithelium then fell off, and the lesion began to take on the character of a typical chancre; the usual train of symptoms followed.

The second case was that of a patient who called the day following a suspicious connection. In this case the genital organs were examined daily. On the twelfth day, three silvery pin head spots such as might be made by touching the surface lightly with the tip of a crayon of nitrate of silver, appeared in close proximity upon the glans penis. On the fifteenth day, the lesion had attained a diameter of a line and resembled a papule of lichen planus; general symptoms followed in due course.

The point of interest in these two cases is the peculiar silvery appearance of the lesion, which may be recognized at so early a stage that contagion may be avoided. The appearance mentioned may last two weeks, and may then yield to the typical features of the chancre.

Two other appearances may be presented in the earliest period of the initial lesion of syphilis. 1. A minute, round, excoriated spot like an erosion, generally of a sombre-red color, and not usually the seat of hyperæmia. The further course of this lesion is characterized by enlargement in area and depth. This lesion is sometimes multiple. 2. The *papule sèche* of French writers, usually seen in cases of retracted or absent prepuce. It may run its course without change of character, or it may become indurated with parchment induration.

In children, said the writer, he had often observed the appearance of the initial lesion described above. In one case, an infant presented a pin-head-sized silvery spot on the tip of the tongue exactly as if a crayon of nitrate of silver had been touched to it. Absolutely no change of texture could at first be perceived, but the lesion rapidly indurated, eventually becoming a large mass.

A paper by **Dr. Duhring**, of Philadelphia, entitled

THE VALUE OF A LOTION OF SULPHIDE OF ZINC IN LUPUS ERYTHEMATOSUS,

was read by Dr. Stelwagon in the writer's unavoidable absence. The formula recommended by the writer was essentially as follows:

℞.—Zinci sulphat.,
Potasii sulphuret, . . . āā ʒss.
Aquæ rosæ, ... ℥iijss.
Alcoholis, ... ʒiij.—M.

A few minims of glycerine may be added with advantage in some instances. The use of this wash should be preceded by that of soap to cleanse the surface from crusts, etc., when these are present. Castile soap is usually sufficient, but sometimes the spiritus saponis kalinus may be used in preference. The effect of the wash is cooling. Three cases were adduced to show the effect of the lotion in modifying the action of spreading lupus erythematosus.

Dr. Piffard, of New York, said that what is wanted in lupus erythematosus is cauterization or scarification; nothing less, he thought, would really effect a cure.

Dr. Atkinson, of Baltimore, said that he had seen a case said to have been cured by internal treatment by phosphorus.

Dr. Van Harlingen, of Philadelphia, said that the treatment advocated by Dr. Piffard would be inappropriate in that condition of the disease in which the sulphide of zinc lotion is of benefit. In one of the cases described by Dr. Duhring, which had also come under his notice, there was a certain amount of infiltration and new deposit at certain points, which was of some duration, and superadded to this was an extensive and acute area, more erythematous in character, of recent occurrence. The effect of the lotion was almost magical in removing this erythematous portion. It might be necessary later to use stronger measures in the older portions of the disease. He would refer to the title of the paper which called attention to the value of the lotion in question as an agent in the management of lupus erythematosus. It does not claim to be a cure.

Dr. Wigglesworth, of Boston, said that lupus erythematosus is the opprobrium of dermatology. Last year he had travelled to Vienna chiefly for the purpose of inquiring if any more efficient treatment had been brought into use there, but had been disappointed in finding the old ineffective methods still employed. He had used chrysarobin, as suggested by Dr. Fox, in some cases with partial success, and would ask Dr. Fox what other treatment he could recommend.

Dr. Fox, of New York, said, in answer to Dr. Wigglesworth, that the internal use of phosphorus with the external application of pure carbolic acid had recently been accompanied by success in his hands.

Dr. Stelwagon, of Philadelphia, said that in one of the cases related by Dr. Duhring which had lately been under his care, carbolic acid had been used to no avail, while scarification had given rise to dermatitis without hindering the spread of the disease.

Dr. Piffard said that dermatitis is just what is wanted. He had used Hardy's treatment of a strong ointment of biniodide of mercury, the object of which was to excite dermatitis.

Dr. Hardaway, of St. Louis, suggested electrolysis.

Dr. Van Harlingen read a paper, by **Dr. Duhring**, of Philadelphia, entitled

A CASE OF AINHUM, WITH MICROSCOPIC EXAMINATION.

The case was one of a negro in West Virginia, brief notes being given together with the results of a careful microscopic examination of the specimen by Dr. Wile, of Philadelphia. The examination went to show strangulation of the member by a cord or other means intermittingly employed.

Dr. Sherwell, of Brooklyn, had inquired of patients from Turks' Island who, though not physicians, had observed cases of ainhum, and the testimony had been that the lazy negroes are those who are most apt to suffer from "ring-toe," and that the popular belief was that the deformity was produced from a desire to shirk work.

Dr. Hardaway, of St. Louis, read a paper entitled

A PAPULAR DISEASE OF THE SKIN,

to which he regretted that he could not give a more exact designation. The patients were mostly children, in whom a chronic eruption occurred of dull, lemon-yellow, semi-transparent, pseudo-vesicular papules, of the average size of a small split pea, without areola, slightly itchy, and leaving no scar. Treatment seemed to have little effect, but in some cases spontaneous recovery took place. The eruption resembles the colloid disease of the skin described by Wagner and Besnier, but is a distinct affection.

Dr. Graham, of Toronto, presented, with photographs, a description of a

PECULIAR NEW GROWTH OF THE SKIN OF THE ARM,

occurring in a woman of forty, and resembling elephantiasis or lymphangioma, but of rapid growth, soft, and diminishing greatly in size when the forearm, from which it hung loose and bag-like, was raised. The growth resembled in some respects certain cases described by Dr. S. C. Busey, of Washington. The writer considered the case to be a dermatolytic outgrowth, with dilatation of the lymph-channels. He asked for advice as to treatment; the growth is increasing rapidly.

Dr. Atkinson, of Baltimore, thought he had seen a similar case; he was inclined to regard it as lymphangioma.

Dr. Piffard suggested, in answer to the writer's inquiry regarding treatment, that electrolysis in successive operations should be employed.

Friday, August 31st, Third Day.

A session was held for the exhibition of microscopic specimens, photographs, etc.

The following gentlemen were installed as

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. Robert W. Taylor, of New York.

Vice-Presidents.—Dr. A. Van Harlingen, of Philadelphia, and Dr. J. E. Graham, of Toronto.

Secretary.—Dr. W. Alexander, of New York.

Treasurer.—Dr. George H. Rohé, of Baltimore.

The Association then adjourned, to meet at West Point, on the Wednesday nearest September 1, 1884.

CORRESPONDENCE.

COLORADO FOR CONSUMPTION.

The following extract from a letter of a very intelligent gentleman who went to Colorado a few months ago on account of advanced tuberculosis, will be found to be of interest:

"I am located at present in a log-cabin at the forks of Eagle River and Brush Creek, in Eagle County, Colorado; elevation 6,400 feet, temperature, at present, between 70° and 80°, with rain about every ten days, and very cool nights. This is part of one of the ranges of the Rockies, and snow on the hilltops of the higher levels can be seen. The three-quarter mile wide stretch of level land running for many miles along the Eagle at this point, is abruptly bounded at the other side by great hills with pine growth, and back of them grassy hills and mountains, where the settlers that come here slowly, propose to "range" their cattle, when they get them. Everything is new here; the irrigating canals have not yet been dug, and the sage-brush, with its hordes of venomous mosquitoes and deer flies, grows everywhere except in the bottoms and cleared patches. I was advised by three different physicians of various localities of this State, that if I desired to get the full benefit of Colorado air, I should have to "rough" it on the mountains. After five weeks in Denver, with marked improvement, I started for Leadville, remained a few days, thence to Red Cliff (the end of the railroad), and thence thirty-four miles by wagon, over many mountains, to the present point, the roughest and most distressing ride one can conceive of. Climbing the mountain trail at high elevation taught me that my lungs were touched—adhesions at least; humanity comes to the relief of man and horse, and we stop to rest every thirty or forty yards. Camping out, though well chilled in my blankets, no evil followed. The nearest post-office is Dotsero, twelve miles away, with a stream to ford on horseback.

Life is of the primitive kind here, there is only a step from my cabin to the wigwam. We do our own cooking, etc.—no women for miles. We live on deer, elk, bear, fresh trout from the Eagle (my first weighed three pounds), and my ranchman host sends me with a shotgun for a rabbit for dinner; coffee, butter, etc., come from Leadville, where these and other articles are unusually high-priced. We sleep *in* blankets, a pair of double, with rubber and hay for mattress.

Dressing a piece of fresh meat, or a trout, hanging it up clean and free from impurities, the piercing sun that scorches my hands and face and lips, till I have to keep to the cabin till they heal, simply renders it drier and cleaner, it does not decay. The dead horse by the side of the trail shrinks up in his hide, and does not rot. Small wonder, then, that my bronchial trouble is also drying up. I am slowly but surely getting well without *treatment* or *medicine* of any kind. My sleep is often unbroken, the great daily loss of phlegm is less than one-fourth, and returning strength and courage reconcile me to the great expense and loss to my little family, for I have been positively pulled up by the roots, and transplanted into a *terra incognita*. Looking on the grave with the utmost equanimity, a few months ago, I am now taking measures to dig a ten-foot hole, and secure a ten-and-a-third acre mineral claim at Carbonate, on a mountain twenty miles away, where prospectors are flocking from all sides on horse, mule, and burso, with scant outfit—the rifle and the frying-pan being the most apparent of the accoutrements. The croppings are the same as at Leadville. Many wonderful cures of persons far gone in lung disease, are noted in Denver. It is a bad place, though, on the whole, when heavy hemorrhages are coming from the weakened patient. The poor skeleton lady, for whom we all threw up our car windows one raw morning near Denver, died in a few days after; and I have seen many coffins put on the trains, of which the newspapers of that great and beautiful city say nothing."

NEWS ITEMS.

MONTREAL.

(*From our Special Correspondent.*)

The Laval Question.—Dr. Desjardins has apparently been successful in his mission to Rome, on behalf of l'Ecole de Médicine et de Chirurgie. Bishop Fabre has received a telegram from Cardinal Simeoni directing that the school be allowed to open as usual. There is great rejoicing among the friends of the old school.

BERLIN.

(*From our Special Correspondent.*)

The German Cholera Commission.—In consequence of the cholera epidemic now prevalent in Egypt, the German Government has resolved to dispatch three members of the Imperial Board of Health for scientific researches on the spot.

According to this plan, which is much favored by the German Crown Prince, Privy Councillor R. Koch and Staff Surgeons Gaffky and Fisches will immediately depart for the land of the Pharoahs.

Their professional brethren in Germany, and I dare say in the whole civilized world, bid them a hearty farewell, and hope they will return from their dangerous task in full health and with rich earnings for our science and for the benefit of mankind.

It is impossible not to draw a parallel with the first similar German commission, executed by Messrs. Hirsch, Knessner and Sommerbrodt in consequence of an outbreak of the plague in southeastern Russia in 1878–79. The difference is obvious. On both sides the same ardent zeal, the same intrepidity and self-devotion, but *there* the last rays of a sort of "pen and ink" era, *here* the dawning morn of a modern practical and experimental epidemiology. May it become a bright day!

Yellow Fever at Pensacola.—Since our last report there have been four new cases of yellow fever, and two deaths at the Pensacola Naval Station. There have been no cases in the town.

Ship Island Quarantine Station.—Dr. Finney, in charge of the Ship Island Quarantine Station, states that there are now twelve vessels in quarantine there, from which nineteen cases of yellow fever were taken; all of these cases were brought from Vera Cruz. The Surgeon-General has also been informed that the American brig Hattie M. Bain, which left Havana for Boston, had a case of yellow fever on board. The vessel was disinfected at Havana.

Yellow Fever at Panama.—During the month of July there were eleven deaths from yellow fever among the foreign population at Panama, and the deaths among the poorer classes of foreigners and natives, which are not made public, were more than twice that number. Great difficulty in experienced in obtaining the mortality reports, as it is clear that if they were made public it would be difficult for the Canal Company to obtain laborers, and it might enhance the cost of labor. The employés of the company are so reticent on the subject that it is presumed that they have orders not to give information.

Yellow Fever in Havana.—There were twenty-nine deaths from yellow fever in Havana last week.

Smallpox in New Orleans.—For the week ending August 25th there were twelve deaths from smallpox in New Orleans.

The Cholera Mortality in Egypt.—The cholera epidemic may be now said to be practically at an end. An official report shows that there have been 27,318 deaths from cholera in Egypt since the outbreak of the epidemic.

There have been 140 deaths among the British troops stationed in Egypt.

Insecurity of the Hospital Quarantine Barge Selden.—According to the *Maryland Medical Journal*, September 1, 1883, the Hospital Barge Selden, to which yellow fever patients are transferred on their arrival at the mouth of the Chesapeake, would seem to be very ill-suited for such purpose. The other day the Steamship Caribbean, bound from Kingston, Jamaica, to Baltimore, was detained thirty-six hours at the Quarantine Station, and complaint being made of this the Surgeon-General explained that the quarantine physician had found it necessary to go to Norfolk in order to procure workmen to repair the barge, "which was in a dangerous condition." Capt. Evans, also, the pilot, who was detained on board the barge for ten days on account of his having brought the infected Steamship Californian up the Bay, says that "the barge is in a most dangerous situation with undertow so strong that the stanchions of the lower deck were wrenched from their fastenings; that the roof let in the weather; that the connections of the watercasks were broken apart and all fresh water lost; that the craft is frail and may go to pieces at any moment; that it is surrounded by dangerous shoals and reefs, and is liable to be knocked to pieces by the first nor'easter that comes along; that the barge itself is an unsafe habitation even in good weather, and that patients cannot be safely conveyed to it." Granting that some portion of this picture is overdrawn there is still evidence enough to show that those who are so unfortunate as to be confined to the barge—both sick and well—are subjected to a most unwarrantable risk. Under no circumstances, even to secure the interior from the danger of the pestilence, is it justifiable to place the lives of those subjected to quarantine in peril.

American Gynecological Society.—The Eighth Annual Meeting of the American Gynecological Society will be held in Philadelphia, at the Hall of the College of Physicians, on Tuesday, Wednesday, and Thursday, September 18th, 19th, and 20th. Papers are expected to be read as follows: *Superinvolution of the Uterus*, by Dr. Joseph Taber Johnson, of Washington; *The Importance of Cleanliness in Surgical Operations*, by Dr. R. Stansbury Sutton, of Pittsburg, Pa.; *Some Points Connected with the Subject of Dysmenorrhœa*, by Dr. C. D. Palmer, of Cincinnati; *An Unusual form of Abdominal Tumor—Three Cases*, by Dr. Thaddeus A. Reamy, of Cincinnati; *Is Extirpation of the Cancerous Uterus a Justifiable Operation?* by Dr. A. Reeves Jackson, of Chicago; *A Biographical Sketch of Dr. Nathan Smith, Founder of the Dartmouth Medical College* (being the President's address), by Dr. Gilman Kimball, of Lowell, Mass.; *The Management of Accidental Puncture and other Injuries of the Gravid Uterus as a Complication of Laparotomy*, by Dr. Charles Carroll Lee, of New York; *A New Method of Operating for Fistula in Ano*, by Dr. Edward W. Jenks, of Chicago; *Ergot; the Use and Abuse of this Dangerous Remedy*, by Dr. George J. Engelmann, of St. Louis; *Congenital Fissure of the Female Urethra, with Extrophy of the Bladder*, and *Menstruation after Extirpation of the Ovaries*, by Dr. Henry F. Campbell, of Augusta, Ga.; *Remarks on Chronic Abscess of the Pelvis*, by Dr. William H. Byford, of Chicago. A discussion on *Death after Labor* will be opened by Dr. Campbell.

AMERICAN PHARMACEUTICAL ASSOCIATION.—The thirty-first annual meeting of the American Pharmaceutical Association will be held at Washington, commencing next Tuesday, and continuing four days.

ARTIFICIAL LIMBS FOR SOLDIERS.—The Surgeon-General of the Army has just issued the following circular:

Congress having appropriated a small sum for furnishing special surgical appliances to those disabled in the military or naval service, the coöperation of surgeons is invited in order that this relief may reach the class of persons intended to be benefited.

This office is desirous of obtaining authentic information regarding all existing cases of severe and unusual injuries, and in reporting such, it will be found useful to bear in mind the following points:

1. As no money commutation is authorized, only such cases need be presented as offer a fair prospect of being relieved by surgical or mechanical appliances.

2. Artificial limbs and apparatus for disabled limbs being otherwise provided for, by law, the injuries here in view are almost exclusively those affecting the head, face, or trunk.

3. As trusses are furnished under special legislation, hernia, when not complicated with other injuries, is not to be understood as covered by this appropiation for *special* appliances.

4. As the appropriation is small, it is proper that it be expended only on the most meritorious cases. It is therefore not intended to furnish appliances which are ordinarily within the means of the individual, nor those that are of a character so perishable that it would be difficult to keep up the supply. Regard is to be had chiefly to the severity of the injury, and the ability of the sufferer, unassisted, to procure relief.

THE AMERICAN PRACTITIONER.—Dr. Theophilus Parvin, on account of his removal to Philadelphia, has retired from the editorial management of this journal, and has been succeeded by Dr. John A. Octerlony.

THE FIFTIETH DOCTORATE JUBILEE OF PROFESSOR BUDGE.—The fiftieth jubilee of PROF. DR. BUDGE has been recently celebrated in Greifswald. Prof. Budge was born in Wetzlar in 1811; moved to Bonn in 1842; was made Professor in the University of Bonn in 1847, and was called to his native place in 1855. Among the honors conferred upon him in view of his services to the profession and on the occasion of his jubilee are the Diploma of the Universities of Berlin, of Tübingen and Krakau, and the Medical Faculties of Marburg, Heidelberg, Königsberg, Brussels, Basle, Bern, Zürich, Leipsig, Erlanger, Strassburg, Breslau, Halle, Giessen and Göttingen, and the President of the Royal Leopold-Caroline Academy of Naturalists, prepared and sent congratulatory addresses, as did twenty young physicians who have recently studied in Greifswald. About 700 of his old pupils sent photographs, souvenirs, and congratulatory telegrams. In the evening, there was a grand torchlight procession, ending with "Gandeamus igitur" by hundreds of voices.

A CHAIR OF HOMŒOPATHY.—A homœopathic physician at Vienna has left a large sum of money for the establishment of a homœopathic chair in the Vienna University, but the Austrian Government has declined to accept it.—*Chicago Med. Journal*, Sept. 1883.

NEW MEDICAL JOURNAL.—We have just received the first number of *El Ensayo Medico*, published in Caracas, and edited by Drs. Dorateo de Armos, F. Monroy Gonzalez, and David Lobo.

HEALTH IN MICHIGAN.—Reports to the State Board of Health for the week ending August 25, 1883, indicate that intermittent fever, dysentery, pneumonia, puerperal fever, neuralgia, and rheumatism have increased, and bronchitis and inflammation of the brain have decreased in area of prevalence.

Including reports by regular observers and by others, diphtheria was reported present during the week ending August 25, and since, at sixteen places, scarlet fever at twelve places, and measles at five places.

OBITUARY RECORD.—On Sunday, September 2d, of paralysis, JAMES DOWLING TRASK, M.D., of Astoria, New York.

Dr. Trask was born in Beverly, Mass., in 1821. He graduated in arts at Amherst College in 1839, and received the degree of M.D. from the University of the City of New York in 1844. Subsequently the honorary degree of M.D. was conferred upon him by the Medical College of Buffalo, N. Y. He settled as a practitioner of medicine in Brooklyn, removed from there to White Plains, Westchester County, some years afterwards, and in 1859 he took up his residence in Astoria, L. I., where he practised his profession up to the time of his death. For some time past his health was poor, but he continued to attend to his professional duties until within a few days of his death. He was one of the founders of the American Gynecological Society, and was formerly Professor of Obstetrics and of the Diseases of Women and Children in the Long Island Hospital Medical College. His contributions to medical literature were of marked value, and his very valuable paper on *Placenta Prævia* received the prize of the American Medical Association, and was published in its *Transactions* for 1855. In 1843, he published, in THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES, an elaborate paper on *Rupture of the Womb*, based on a study of over four hundred cases, which is still the best monograph we have on the subject. His last published paper was a very careful study of *Mushroom Poisoning* and appeared in THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES for April, 1883.

OFFICIAL LIST OF CHANGES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 27 TO SEPTEMBER 3, 1883.

WAKEMAN, W. J., *First Lieutenant and Assistant Surgeon.*—Assigned to temporary duty at Fort Sidney, Nebraska.—*Par. 2, S. O. 92, Department of the Platte, August* 28, 1883.

SOME DISEASES OF THE FEMALE ORGANS OF GENERATION, CHARACTERIZED BY NEW GROWTHS.

A Clinical Lecture, delivered at the Long Island College Hospital, Brooklyn, N. Y.

BY ALEXANDER J. C. SKENE, M.D.,

SURGEON TO THE HOSPITAL, AND PROFESSOR OF GYNÆCOLOGY IN THE LONG ISLAND COLLEGE HOSPITAL, BROOKLYN, N. Y.

(Reported by EDWARD DEVELIN, M.D.)

(*Concluded from p.* 256.)

HYDRO-SALPINGITIS: DROPSY OF THE FALLOPIAN TUBE.

GENTLEMEN: This specimen which I here show you is the uterus and ovaries of a woman who has borne children, and has had a severe pelvic inflammation. I desire to call your attention to the inflammatory exudation upon the peritoneum, with which the uterus and ovaries are covered, and which so well illustrates the exudation or product of pelvic peritonitis of which I have so often spoken. You will observe that it is a plastic exudation thrown out over and around the uterus both in front and behind. At one point below, however, I can show you a small portion of normal membrane. These shreds which I now hold up on the tenaculum are this plastic material which has become organized. On searching for the ovaries, I find something which might be them, but it does not feel like them, because it is so covered with this exudation. I now find one of the ovaries, which is decidedly diseased, and which looks like a commencing cystic degeneration of this body: you will observe that it is somewhat irregular in shape, it being also modified by this exudation. Now, in my didactic lectures, I have endeavored to convey to you the idea how this exudation produces pressure upon the ovaries, which is here well illustrated. This pressure gives rise to what is often termed ovarian neuralgia.

On turning the uterus over, we now come to the most interesting point of this specimen. Now, passing from the fundus uteri, I find one of the Fallopian tubes immensely distended, becoming more so as we pass up towards the fimbriated extremity—in fact, it is so much distended that it appears like an ovarian cyst. I find it exceedingly difficult to trace this Fallopian tube at its lower extremity, owing to this extensive inflammatory exudation. This condition which we have here, as represented in this Fallopian tube, is that known as hydro-salpingitis, or dropsy of the Fallopian tubes. I believe it to be in this instance the result of a preëxisting salpingitis, some inflammatory process causing a dropsical effusion upon the mucous surface of the tube, filling up and distending the tube, as shown in this specimen.

I had the opportunity of seeing a case of this kind with Dr. Cushing, who had made the diagnosis ovarian dropsy. He aspirated the mass, and found a clear-looking fluid. The question then arose, Had he aspirated a small ovarian cyst or a dropsical tube? The doctor was fortunate enough to be able to verify the correctness of his diagnosis by what you can sometimes do; and that is, he introduced a small probe into the uterus, and succeeded in passing it into the Fallopian tube, whence, by dexterous and gentle manipulation, the probe could be felt through the vagina within the tube. I have also been called in consultation in some cases where this same condition of things has existed, there being a fluctuating tumor discovered in the cul-de-sac of Douglas which has suddenly disappeared upon a gush of this clear fluid passing from the uterus. In one case, this condition existed for two or three years, and about once in three days this fluid would pass from the vagina. We were perfectly certain the fluid came from the uterus, for, on making pressure upon the tumor, it caused it to escape from the uterus, as we could distinctly see. In that case, I tried again and again to pass the probe into the Fallopian tube, but could not succeed, as the distention of the tube occurred at some distance from its entrance to the uterus.

Dr. Cushing aspirated in his case several times, but failed to effect a cure by this means; he finally opened the vaginal wall, incised the tube, and evacuated its contents, and then injected the cavity with iodine, by this means effecting a cure. The wound healed kindly, and the patient was kept under observation for a long time, but there was no tendency to a return of the difficulty.

When all ordinary means fail, and the patient suffers so that her usefulness is markedly impaired, the tube should be removed. Lawson Tait is the great authority on this operation, which is performed in about the same way as ovariotomy.

ATROPHY OF THE OVARIES.

The specimen which I here present to you—the vagina, uterus, and ovaries—illustrates a point which I think well worthy of consideration. You will notice that the ovaries have become atrophied, being about one-third of their normal size; they look like the ovaries of a very old person, and the only reason I have for believing them not to be those from a person of advanced age is that I find the uterus to be almost normal in size, and I am now informed that the woman from whom these were taken was only thirty years of age. This is a splendid illustration of early or premature atrophy of the ovaries. But with this statement comes the question, Did she not have an arrest of development of the ovaries? No; I know she performed at one time all the functions of a perfectly healthy woman, and whose ovaries are normal; I know that she at one time menstruated naturally, this function gradually becoming less, and finally ceasing altogether. The mammary glands were fully developed, as was also the pelvis, and I am informed that the voice was natural.

We have here, then, in this specimen, an atrophy of the ovaries which would be normal if it occurred in a woman at about fifty or sixty years of age, but in this case it is abnormal, occurring at so early an age. You will here observe, on inspecting the ovaries, that there are small scars, indicating that the woman had ovulated again and again, and until the ovaries took on this process of degeneration. Why this degeneration should have occurred I have no means of knowing; it may have been caused by some derangement of nutrition.

I show this specimen to you, however, simply because I know it to be atrophy of the ovaries occurring in a woman only thirty years of age. It also illustrates another point, now a well-established fact, namely, the influence of the ovaries over menstruation; the uterus, you can all observe, was large enough to perform the function of menstruation, but being deprived of the stimulating influence of the ovaries, menstruation at once ceased to exist. This is an exceedingly interesting and rare specimen, from which a lesson of great importance is to be learned.

EPITHELIOMA OF UTERUS.

This patient is fifty-three years of age, is married, and has borne several children. She passed the menopause several years ago, but about one year ago she began to suffer from a discharge from the uterus, at first serous and slightly pinkish in character, which gradually became more sanguinolent; and for the past month or two she has had almost a constant bloody discharge from the vagina, which has been of a somewhat offensive odor. She has also had several attacks of hemorrhage, which have been quite marked. Through all of this, her health has been fairly good, as it always has been, and she has suffered but very little pain. She has been seen by a physician, who discovered the nature of her disease, and sent her to us for treatment.

On making digital examination, I discover that the vagina is not more than two and a half inches long, and I find at its termination an irregular mass which almost fills the middle portion of the pelvis. In the centre of this mass I find an opening, through which I can with some difficulty pass my finger, and beyond that I find quite a little cavity, the walls of which appear to be of the same irregular character, the external or vaginal surface of this mass being quite irregular and slightly soft to the touch, but the structures below its immediate surface are quite dense, the diseased mass itself being immovable under any ordinary pressure.

We have here, then, the physical signs, as obtained by the touch, of epithelioma far advanced. On placing the patient in Sim's position, and elevating the perineum, I find this mass is exceedingly vascular, so much so that touching it lightly produces hemorrhage; in other words, it has all the appearances of this form of malignant disease. So marked are the physical signs in this case that the diagnosis is absolutely certain.

The question of treatment now presents itself to our consideration, and that involves two important questions—First, what is the general condition of the patient? Is it such that she would bear an important surgical operation? This can be answered in the affirmative: her general health is good; she is not yet suffering from the marked cachexia which we see in the advanced stages of malignant disease. So far, then, her condition is favorable to an operation. The next question is, Can we remove this diseased mass with any advantage to the patient? This is a question that, I am sorry to say, must be answered in the negative. Operations in cases of epithelioma can only result in benefit to the patient as a rule when you can remove the entire diseased mass, when you can go beyond it, so that your line of incision will pass through normal tissue. If this can be done, then there are hopes that you will retard the progress of the disease, and, in a certain sense, cure the patient for the time being. The disease may return, but still you prolong the life of the patient, relieve her suffering, and give her comfort. When that is not possible, then the best that you can do is to remove portions of the diseased mass, the benefits to be derived from this being really *nil*. In fact, I am inclined to believe that, in place of arresting the progress of the disease, the probabilities are that you will stimulate it to more rapid progress. There is only one good reason why we are sometimes led to operate in these far advanced cases, and that is when the hemorrhages are repeated and extensive. We can then, by means of the galvano-cautery, remove as much as possible of the diseased tissue, and cauterize that which remains, and so, by lessening the mass of diseased tissue, lessen the liability to hemorrhage for a time; or we may take the curette, and remove all that we possibly can, and then cauterize the base of the diseased mass, and in that way accomplish the same object.

In this case, the hemorrhage has not been excessive, although rather continuous, and I think that we will act the wiser part by avoiding all operative interference. We can, however, control the hemorrhage, and by using the tampon relieve the patient from the inconvenience of this offensive and somewhat irritating discharge. A favorite method of mine in the management of such cases is to employ the tampon of marine lint, allowing it to remain for forty-eight hours or longer before changing it. The effect of this is to produce a little gentle pressure upon the bleeding surfaces, and thus check the tendency to hemorrhage; at the same time, the marine lint absorbs the serous discharge, disinfecting the parts, and so keeps the patient free from the constant discharge, which is at least a great comfort. Beyond this I know of very little that we can do for her, except to give opium if she has pain, and keep the bowels regular, for if she be permitted to become constipated, movement of the bowels will cause great distress. In short, we can only palliate, not cure, in these cases. You will remember how frequently I have cautioned you against the use of opium in painful uterine disease, because of the great tendency to establish the opium habit; but in a case like this, which must sooner or later terminate fatally, it is then right and our duty to relieve the sufferer by the use of opium in quantities sufficient to control the pain.

FUNGOUS GROWTH IN THE UTERUS.

I now call your attention to this specimen of fungous growth which I have just removed from a private patient of Dr. Rand's; it illustrates these growths, which we so often find, and is simply a mass of fungosity, well named. The patient is sixty years of age, and this is the second time I have operated upon her. About five or six months ago, I removed a mass similar to this, which relieved her of the hemorrhage from which she was then suffering. The hemorrhage again returning, Dr. Rand brought her to me, and I operated in the same manner as before. As a rule, these fungosities are benign, are easily removed, and they do not usually return. The line of demarcation between this growth and that of an epithelioma is not easily determined either by the clinical history or the gross appearance of the fungosities; but where it occurs in advanced life, I am always suspicious. Dr. Thallon examined the previous specimen that I removed, and pronounced it epithelioma, and the fact that it has returned so soon favors that diagnosis. While I have seen a hundred or more cases of epithelioma of the cervix, I have only seen five cases where it occurred in the body of the uterus: one of these is recorded by Dr. Thomas in his work, the case coming under my observation at the time. Since that time I have seen four others.

The age of this patient, and the fact that this growth has so soon recurred, makes me suspicious that she is going to develop or has developed an epithelioma. It, however, makes but little difference, so far as the management is concerned; it is good treatment to arrest the hemorrhage by removing the morbid growths with the curette, whether they be benign or malignant.

ENDOMETRITIS POLYPOSA.

This lady now before you is fifty-three years of age, has been married twenty-eight years, but has never borne children. Two and a half years ago, she was operated on for what was diagnosticated endometritis polyposa. She passed the menopause ten years since. She now tells us that she has pain in the back, pain in the left inguinal region, and slight leucorrhœa, which is somewhat sanguineous at times.

Upon examination, I find the uterus in the normal position, as near as I can make it out; but I find it runs off a little on one side as if there was a little fulness above the vaginal junction on the left, as if we might have a little interstitial or subperitoneal fibroid. This uterus I find to be over three inches in its long diameter; so we have here an enlargement of the uterus which is not symmetrical. It is a question whether this increase in size is due to a small fibroid; it is rational to suppose it is; and I might here state that these growths are more apt to occur in sterile women. Even if we have a fibroid there, it would be latent, as they generally subside at the menopause, and waste away with the final involution of the uterus, so that I hardly think the cause of her pain and bleeding is due to that. I would rather be inclined to think that it is a recurrence of this fungosity of the mucous membrane of the organ.

Dr. Stuart informs me that passing the sound causes hemorrhage, which is arterial, so that in all probability it comes from this fungous condition. Now I would venture an opinion that we have a recurrence of this growth which we removed two years ago, and which was at that time supposed to be benign. At this age, it is very probably a commencing epithelioma of the mucous membrane of the body of the uterus. We may, however, remove it by the use of the curette, and examine it microscopically, and see if the structure of the growth agrees with the clinical history. When we have a uterine hemorrhage in a patient fifty-three years of age, it strongly indicates malignant disease; but epithelioma of the mucous membrane of the body of the uterus is rare, and we should obtain all possible evidence before positively making a diagnosis.

POLYPOIDS OF THE UTERUS.

This patient is thirty-nine years of age, has had four children and two miscarriages. For twelve years she has been suffering from menorrhagia. Five years ago she was operated on for this difficulty, but within the past three months it has returned. She had at that time a "vascular tumor" of the urethra removed. The question for us to settle is, why she has menorrhagia. This we will endeavor to do by an examination. I find that she still has the remains of that caruncle of the meatus urinarius, and I have no doubt that has something to do with the pain and tenderness which she complains of, The uterus is slightly larger than normal, and by passing the curette I find that the walls of the uterus are covered with a polypoid material. You noticed that I passed the curette and removed some of this substance, which shows that the hemorrhage is due to these polypoid growths. These we will carefully remove with the curette, and in that way arrest the menorrhagia.

EPITHELIOMA OF THE VULVA.

This case is one of epithelioma of the vulva, upon which I operated some weeks since, and I now bring her before you to show the result of the operation. You will remember that I removed the growth with the cautery at that time.

The patient states that she is feeling well, and you will notice that the wound has almost cicatrized. There is, however, one spot which is not completely healed over, and I am rather suspicious of that point. I am rather inclined to think that there is yet a trace of her old difficulty remaining upon that side. We will, however, await further developments.

LABIAL CYST AND STENOSIS OF THE INTERNAL OS.

This next patient whom I present to you is a married lady aged thirty-eight years, has menstruated perfectly regular, but there seems to be some trouble with the labia on the left side. On examination I find here a labial cyst; Dr. Cushing informs me that he punctured this cyst some time ago, and secured that clear gelatinous fluid from it which is so characteristic of these cysts. These, however, always recur if you only puncture them; in this case it was punctured simply to confirm the diagnosis. When this cyst becomes a little more distended, so that the mucous membrane will be a little less vascular, the Doctor will make a free incision and evacuate its contents, and thoroughly cauterize the cyst-walls with carbolic acid and iodine, sponging it out thoroughly and introducing a pledget of lint saturated with the acid and iodine, until it sets up a suppuration; then, removing it, the suppuration will entirely destroy the secreting membrane. That will be the end of it.

This patient had also another difficulty which Dr. Cushing found on examination. He found she had a true stenosis of the internal os. Now normally the internal os is smaller than the canal elsewhere, but this was abnormally constricted. This is an exceedingly rare condition; it is often spoken of, but seldom met with. When you have a flexion of the body of the uterus, you have an apparent stenosis of the internal os, but if you straighten the uterus itself, you will find the canal is as large throughout as it should be. We do, however, find true stenosis. That such a thing does occur I have demonstrated, not by the use of the sound alone, but by the sea-tangle tent; the normal tissues giving way readily as the tent expands, but at the internal os the resistance was such that the tent, when removed, was found with a line around it, indicating plainly the constriction at the internal os. This was the case here, and Dr. Cushing adopted one of the most reliable means of treatment, which is by gradual dilatation by repeatedly passing the sound. Dr. Cushing here tells me that I am slightly in error upon that point, however, as instead of this means he used forcible dilatation with the small uterine dilator. That is a method which answers admirably also, and as proved in this case; for this lady has now passed two weeks over her regular menstrual period, so that I have no doubt her sterility was due to this stenosis of the internal os. I am satisfied that she is pregnant, for I know of no reason why one who is in such perfect health as this patient should have passed over her regular menstrual period, unless the cause was gestation.

Now in regard to this forcible dilatation I may be misunderstood, and some of you may think I am opposed to this forcible dilatation of the uterine canal from what I have said on other occasions; but I am not. On the contrary, I know it is a safe and reliable method of treatment if carefully performed and not carried too far. It is a very satisfactory way of treating this difficulty. It is a method I adopt very frequently, especially with the external os, and no harm comes from it. But if you carry one of these jack-screws up to the fundus uteri and then forcibly dilate the canal until it is an inch in diameter, you may do harm; this is doubtful treatment, and should be avoided unless you feel disposed to take the consequences, and your patient is similarly inclined.

VASCULAR TUMOR OF THE MEATUS.

(History furnished by Dr. Stuart.) This young girl, seventeen years of age, came to the hospital last Thursday, stating that she was suffering from disease of the sexual organs, and which first made its appearance when she was eleven years of age. This to me was rather a formidable and frank statement for one of her age to make. Upon investigation, however, I found between the labia a flat, bright-red mass not very thick, not much thicker than my finger-nail, very tender and bleeding upon the slightest manipulation. The examination was difficult, owing to the exquisite tenderness, but the growth appears to arise from the meatus urinarius; had been developed slowly, and during its growth it had been subject to the pressure of the labia, which gave it this flat, thin shape; had it not been owing to this pressure it would probably have developed into a circular mass about the size of a pea. She has some pain from urination but not very much; she commenced menstruation when fifteen years of age, this function being perfectly normal.

You see here how perfect this growth is, this is one of the most typical cases I have ever seen of a vascular tumor of the meatus, the caruncle of our books. Here you see I can lift it up, it is of an extremely bright red, contrasting very strongly with the rest of the normal membrane surrounding it.

There are two or three ways of operating in these growths. I will, however, simply seize it with the ordinary forceps, and then draw it forward and make traction upon the peduncle. As I do this, you notice how extremely friable and vascular this growth is, and even with the most delicate manipulation it bleeds profusely; we will now apply the actual cautery to the base of the peduncle; but, even in spite of this, you notice that I cannot entirely control the hemorrhage and am therefore compelled to ligate it just above the point where I used the cautery. The difficulty in removing these growths is this: the moment you seize them they break off, being so friable, and if I am careless in using the cautery, I shall do a great deal of damage, as I shall make scar-tissue around the meatus which in time would cause stricture, and in two years hence she would be worse than she is now; this is why I used the ligature in place of applying the cautery more extensively: I was unable to bring down enough of the normal mucous membrane to make a pedicle, which could be properly divided with the cautery. It is not sufficient to control bleeding to simply touch the surface with the cautery; the blood-pressure will throw out the little coagula which you form with your lightly applied cautery; but when the mucous membrane gives you a pedicle which you can thoroughly cauterize, then it will arrest the hemorrhage, and that is the end of it. When you cannot do that, as in this case, then you will need to apply the ligature; the advantage of the cautery is that it is not very painful, whereas the ligature is quite so. With the cautery, you completely destroy the tissues so that they can no longer ache; but with the ligature, until the tissue dies from pressure, it is extremely painful. This same treatment is employed in hemorrhoids, and we have a chance to study its effects. Now, on account of that tenderness, I am in the habit of using both—ligature and cautery together; ligating the hemorrhoids and then cauterizing them, thus destroying them absolutely.

Now, this case will have to be watched, as the growth may sprout up again; they often do. The pathology is the same as in the mucous polypi. Some little circumscribed irritation sets up a proliferation which goes on growing.

This is one form of the vascular tumors of the meatus, and the rarest of this class.

ORIGINAL ARTICLES.

REMARKS ON THE IMPORTANCE OF HAVING TRAINED NURSES FOR THE SMALLER TOWNS AND RURAL DISTRICTS, AND THE PROPER METHOD OF SECURING THEM.

BY S. D. GROSS, M.D., LL.D., D.C.L.

"Homo sum; humani nihil a me alienum puto."

HAVING long entertained the conviction that good nursing was an indispensable aid to the successful treatment of diseases and injuries, and conscious how little interest the profession and the public felt on the subject, I considered it my duty during a visit I made to Europe, in 1868, to make myself fully acquainted with its various and multifarious requirements. For this purpose, I examined many of the prominent hospitals and training-schools for nurses, and, after my return, embodied the results of my observations and reflections in a report which, the following year, as chairman of a committee appointed at my instance the previous year, was submitted to the American Medical Association at its meeting at New Orleans. The report was accompanied by a resolution, making it incumbent upon the president and secretary of the Association to transmit a copy of it to every State and territorial medical society in the Union, with a view of enlisting their coöperation in the establishment of schools for the training of nurses for hospitals and private families, in accordance with the principles therein advocated.

In order to impart thorough scope and efficiency to this scheme, I suggested that district schools should be formed, and placed under the guardianship of the county medical society, the members of which should make it their business to deliver, at such time and place as might be most convenient, instruction in the art and science of nursing, including the elements of hygiene, and every other species of information necessary to qualify the student for the important, onerous, and responsible duties of the sick-room.

The report bore good fruit; it served to arouse attention to the subject on the part both of the profession and the public, and soon led to the formation of training-schools for nurses in some of our larger cities, and, among others, to the admirable ones at New Haven and on Blackwell's Island, New York; but it failed of its object in the rural districts, where trained nurses are just as much a necessity as anywhere else. In order to recall attention to a matter which every intelligent person must regard as one of vital importance, I offered the following preamble and resolution to the consideration of the Medical Society of the State of Pennsylvania at its meeting at Norristown last May, and to the American Medical Association at its meeting at Cleveland in June:

"*Whereas*, Good nursing is of paramount importance to the comfort of the sick and the restoration of their health, and

"*Whereas*, The subject is one which strongly addresses itself to the common sense and kindly sympathy of every intelligent member of society; therefore,

"*Resolved*, That this Association, fully recognizing the importance of the subject, respectfully recommends the establishment, at every county town in our States and Territories, of schools or societies for the efficient training of nurses, male and female, by lectures and practical instruction, to be given by competent medical men, members, if possible, of county medical societies, either gratuitously, or at such reasonable rates as shall not debar the poor from availing themselves of their benefit."

This resolution, it will be perceived, embodies all the essential features comprised in the one offered at the meeting of the Association in 1869, and I now recur to it with the view of making some practical comments upon it which the medical press of the country has failed to do. Until the present arrangement, by which the Association has a journal of its own, went into effect a few weeks ago, many a valuable paper in its *Transactions* never saw the light of day.

In the first place, I desire to bear testimony to the fact that nursing is not only an extremely useful, but a highly honorable pursuit worthy of the ambition of any respectable person, whether man or woman. Trained nursing is rapidly assuming the form of a dignified profession. It is no longer a menial occupation, but an art and a science. A well-educated nurse must necessarily be a person of refinement and of more or less culture. Such a nurse commands high wages, or, to put it in a more proper way, high fees, is much sought after, and, like the medical attendant, is entitled to the respect and confidence of the family in which he or she renders the service. A nurse often becomes the life-long friend of a patient, and cases have repeatedly occurred in which large legacies have been left for important services rendered in severe and protracted sickness. These remarks are more especially applicable to female nurses, who everywhere constitute the great majority of this class of persons, and in the succeeding discussion I shall, in order to avoid useless repetition, confine myself to that sex.

The chief qualities of a nurse are perfect health, refinement, neatness of person, correct habits, kindness of heart, patience, power of endurance, a good temper, a discreet tongue, good judgment, and alertness of mind. Such a combination of qualities is rare, but where it is present, and has been improved by a rigid course of training, it fulfils the very highest requirements of the sick room. Endowed with such an array of gifts, a nurse is capable of doing an amount of good in combating disease in a degree hardly inferior to that of the medical attendant himself. She diffuses light and courage and sympathy in all her acts and movements, and thus robs disease of half its fears and pangs. An indifferent, poor, or untrained nurse, on the other hand, is too often a source of positive mischief; her want of knowledge is incessantly at fault; she worries and frets not only the patient, but every one around her; everything is out of joint; and, instead of being a blessing, she is too frequently only a nuisance. "For the want of timely care," says Armstrong, the poet-doctor, "millions have died of medicable wounds;" and millions, I am sure, die every year from a want of proper nursing. A good nurse is the right hand of the physician. If his injunctions, in the way of medicine, food, drink, and other necessaries, are not faithfully carried out during the intervals of his visits, how will it be possible for him to combat disease successfully? In many cases, the recovery of the patient is due more to good nursing than to the skill of the physician. When I come to die, let me have plenty of light and pure air in my room, and at my bedside a kind and accomplished nurse, a member, if possible, of that noble sisterhood, the Sisters of Charity, who are doing everywhere such noble work in the interest of the sick and the dying.

The requirements of the sick-room are numerous and diversified, and embrace a knowledge of everything that can conduce to the comfort and recovery of the patient. The first duty of the nurse is to carry out with unwavering fidelity and punctuality the instructions of the medical attendant: this is a sacred duty, and should on no account be departed from, unless unexpected intercurrent circumstances render it imperatively necessary. The relations between the nurse and the patient should be of the most friendly nature. She should move about the chamber, not on tiptoe, but as noiselessly as possible; wear a cheerful countenance, even in impending danger; express herself gently in a few, well-chosen words, and perform every needful duty, however menial or distasteful, with promptness and alacrity. She must not lose her temper or show feeling, even if the patient be unreasonable, fault-finding, or over-exacting, always bearing in mind that these are common effects of disease, and that she must make the best of them. She must not indulge in gossip or tattle, but know and feel that the secrets of the sick-room are sacred.

I would lay great stress upon what I regard as the æsthetics of the sick room—a word which to me has a very high significance. The dictionary defines æsthetics as the science of the beautiful—the beautiful in nature and in art. The sick man's chamber has rarely about or in it anything of the æsthetic; on the contrary, it is generally disgracefully unæsthetic; in a state of confusion worse confounded; one thing here and another there, where they have no business to be, if they be not indeed a source of positive annoyance. Nothing can be more disgusting than to see half a dozen vials and pill-boxes piled upon the table or bureau directly under the patient's eye; a plate, cup, knife, or spoon here or there; a soiled napkin on the bed, or on the wash-stand; a slipper out on the floor, or a chair, stand, or some other piece of furniture out of place. Such disorder cannot fail to make a disagreeable impression upon the patient, and is a disgrace alike to the nurse and to the medical attendant. Each should aim to produce the most agreeable impression upon the poor sufferer. It is bad enough to be sick, but to be shut up, perhaps in a small, ill-ventilated room, filled with unpleasant odors and distasteful surroundings, is unbearable, and little short of a crime.

The educated nurse must have a competent knowledge, 1st, of the general principles of hygiene; 2dly, of the effects, doses, and modes of administration of the medicines in most common use; 3dly, of the nature of food and drink, and the proper methods of preparing them for the sick; 4thly, of the different poisons and their antidotes; 5thly, of local remedies, as leeching, cupping, blistering, bandaging, poultices, lotions, antiseptics, and ointments; and, 6thly, of the manner of handling the patient, of making up his bed, and of changing his body-clothes. If, superadded to this knowledge, a nurse can have some idea of the nature and treatment of the more common diseases, very well, but such knowledge is by no means indispensable. A little knowledge is here, as everywhere else, often a dangerous thing. Dr. Rush used to tell his students that no physician should be permitted to engage in practice unless he had served six months in the kitchen, so important did he consider a knowledge of the art of cooking.

To educate nurses for the rural districts and villages, all that is necessary is to establish a central office or bureau at every County Town in each State and Territory, and to place it under the charge of its medical society, which should select two or at most three of its members to give the necessary instruction. One, for example, might take charge of the various matters comprised under the head of requirements of the sick-room, including hygiene and the nature and preparation of food; another, the mode of examining the patient as to the condition of his tongue, pulse, countenance, skin, temperature, posture, and excretions; the mode of administering medicines, their doses and actions; poisons and their antidotes; while a third might busy himself with surgical, obstetrical, and gynecological appliances and dressings, including the treatment of hemorrhage.

Where no county society exists, the same object may be attained by the banding together of any two or three competent physicians in the place. Notice of the time and place of meeting should of course be given in the public prints, and also by card. A small matriculation fee should be charged, and also, where possible, a small fee for each of the instructors, to assist in defraying expenses. The teaching should be as practical as possible—essentially practical—each pupil being obliged to perform her work in the presence of her instructor, not once or twice, but again and again. Free use should be made of the blackboard. The outfit of such an establishment need not exceed fifty, seventy-five, or, at most, one hundred dollars. There should be frequent examinations, and at the final one a certificate of competency should be awarded to the successful candidates.

If the plan now suggested be faithfully carried out, as I confidently believe it may be, either as here presented, or with such modifications, changes, or alterations as circumstances may render necessary, it cannot fail to be instrumental in saving many lives, in preventing much suffering, in inspiring hope in the sick, and in imparting confidence to the professional attendant. If this plan succeed, I shall feel that I have accomplished the greatest work of my life.

To aid the pupil in her efforts at acquiring knowledge, she should avail herself of a proper text-book. Of this class of works I have now six lying upon my table, and, after a careful examination, give the preference, as to completeness, to the *Hand-Book of Nursing*, published under the direction of the Connecticut Training-school for Nurses. *A Manual of Nursing*, prepared for the Training-school attached to Bellevue Hospital; *Anderson's Lectures on Nursing*, and *Cullingworth's Manual of Nursing, Medical and Surgical*, are also excellent productions, worthy of a place in the library of the nurse and of the physician. Any of these books may be obtained of Blakiston, Son & Co., 1012 Walnut Street, Philadelphia, at one dollar a copy. *A Manual for Hospital Nurses* has been issued by Mr. Edward J. Domville, of London, and is now in its fourth edition; and there is a brochure, entitled *Notes on Fever Nursing*, from the pen of Dr. James W. Allan, of Glasgow, reprinted in Philadelphia. Much valuable information will be found in the *Notes on Nursing*, by Miss Florence Nightingale, published soon after her return from the war in the Crimea, where she earned so much glory by her efforts to assist the sick and wounded.

I could wish that this paper, imperfect as it is, could be widely disseminated, in order to arouse the attention of the profession everywhere to the importance of the subject of which it treats. Unless this be done, and it can be done only through the aid of the medical press of the country, it will signally fail of its purpose.

A HYPERTROPHIED RIGHT LOBE OF THE LIVER MISTAKEN FOR A FIBROID TUMOR OF THE OVARY.

BY JOHN L. ATLEE, M.D.,
OF LANCASTER, PA., LATE PRESIDENT OF THE AMERICAN MEDICAL ASSOCIATION.

MISS A. E., a single lady, aged about 39, who for many years has been a teacher in our public schools, consulted me four or five weeks ago, soon after the school vacation commenced, about a tumor which was developing in the lower portion of the abdomen. She had always menstruated regularly, and with the exception of slight dyspeptic symptoms had always enjoyed good health, and never missed a day from her school. Within the last three months, however, she found herself becoming more and more emaciated and had an unusual feeling of debility. Her color was good; tall and well-formed, with always a good appetite and generally regular bowels, but occasionally had some diarrhœa, and some pain like colic, for which she required an anodyne.

Upon examination I found a hard tumor occupying the centre of the hypogastric region, extending as high as the umbilicus and to the iliac regions, especially the right. It was very hard, but slightly movable from side to side, and this movement did not influence the uterus. The brim of the pelvis on that side was occupied by the mass, although it did not descend into the pelvis. Her waist was of the normal size, with no bulging above the umbilicus. She was sensible that it was increasing rapidly, and wanted relief. I diagnosed a fibroid tumor of the right ovary, and if she wanted to be relieved I would operate.

After the usual preliminary measures had been carried out, and the exhibition of the anæsthetic, I commenced the operation at eleven o'clock A. M., August 22d, in the presence of Drs. Atlee, Jr., Ehler, Welchans, Roland, Rohrer, and William A. Atlee, Jr., and Mrs. Dr. Wilson and her student, by the usual incision in the median line, and exposed the peritoneum, which was dark and very vascular; upon laying it open there was a small escape of ascitic fluid and behind it was a large, chocolate-colored mass, very firm and slightly nodulated, which proved to be an enormous right lobe of the liver! I passed my fingers up and felt the left lobe with its sharp edge, soft, and apparently healthy. Whether it was wearing a tight corset, or from some other cause, the morbid development was towards the pelvis, as above the umbilicus there was nothing to indicate the presence of a tumor. Here was a dilemma which brought the operation to an abrupt conclusion, and the only thing to be done was to close the wound very carefully and put the patient to bed. I think it is a case of encephaloma, not yet fully developed, in the lower lobe of the liver.

I have never, in all my diagnostic experience, been so completely deceived, and I hope your readers will profit by my mistake. It is often in that way we gain our knowledge.

LIMITATION OF INFECTIVE DISEASES, WITH SPECIAL REFERENCE TO PROPHYLAXIS.

By EZRA M. HUNT, M.D.,
PRESIDENT OF THE AMERICAN PUBLIC HEALTH ASSOCIATION.

THE cure, the limitation, and the prevention of disease are so allied to each other that the physician and the sanitarian are excusable for not being very anxious to define with accuracy how much belongs to the particular sphere of each. In each there are so many things we do not know, that some are very much inclined to doubt as to the certainty of what we do know, or to discredit our ability of control. While it is desirable in every case to understand causation, we are not to forget that great progress can be made in actual practice, both preventive and remedial, when we may not be fully able to explain the causes of the disease or the *modus operandi* of the remedy. Those who are most accurate in their knowledge as to results, are the ones most likely to seek for and ascertain causes. The ability of quinine to cure ague is not disputable, because we are not sure how quinine acts. The one who witnesses its action will be most inquisitive as to how it acts. Of late years we have been inquisitive of etiology, as if all progress in treatment were dependent thereupon. Surely we would neither discourage nor underestimate this radical method of advancing both science and art. But in the mean time we would remind ourselves of the substantial progress that has been made, especially with those diseases which tend to become epidemic. While not having all the details of relation between filth and specific contagions, it was a great advance when we came to be impressed with new definitions of cleanliness, and to insist upon it in details, as a part both of the prevention and treatment of disease.

There can be no question that the growth of professional sentiment as to the need of dealing with all surroundings, and with all that relates to the surface of the individual to the degree of technical and enforced cleanliness has made a great advance, both in the limitation and the treatment, especially of communicable diseases.

Our next confidence in our power to prevent the spread of disease, has been in the appreciation of what thorough *isolation* means, how it can be accomplished, and how effective it is in controlling the spread of contagions. In all well-regulated communities, and in all well-informed professional minds, it at once provides for the patient on a separating basis, by immediate hygienic conditions, dilutes or disintegrates the materies morbi, and protects others therefrom, while it is afforded the best opportunity to hasten through the stages of its ephemeral vitality. It has thus become an essential of professional duty to know accurately how to carry out this isolation, how to enforce it, not only as to persons, but their fomites and secretions. It has not only aided us to identify the dejections of cholera and typhoid fever as conveyancers of the contagion, but led us to study the respective distances at which various diseases are communicable, and to have in the aggregate quite positive information and very satisfactory results from the application of the system. It can almost be said that the physician who understands this and the practical application of hygienic methods, scarcely fears that cholera, typhoid fever, scarlet fever, etc., will assume an epidemic character. But the details are often difficult of enforcement.

Another principle that has not been enough enforced is that, in order to secure immunity from attack, it is as *feasible* to deal with individuals as it is with surroundings as a means of preventing the spread of disease. In a sense, there is a difference in inside as well as outside cleanliness among individuals as among places. Nay, more, the old experience as to inoculation, after due preparation of the system, shows at least that the virulence of a disease can be modified by preliminary care. The contagions seem to find much more to feed upon or to fructify them in some than in others. There is reason to believe that this difference is not beyond the reach of human ken, and that the principle of individual sanitation will come to the aid of other practices for the amelioration of disease.

But we are glad to see a still more important principle than either isolation or personal cleanliness now being pushed into prominence.

A communication and an editorial in THE MEDICAL NEWS have recently and forcibly presented this idea. It is a little strange that Prof. Binz and others who have had similar views as to the action of quinine had not sooner conceived the idea that not only it, but other medicaments might be applicable in the direction of systematized prophylaxis. So soon as we began to come to some definiteness of knowledge as to wherein consists the specificity of some of the contagions, it was very natural to inquire whether we could not, in some way, interfere with the decomposition or the fructification of the plant or animal life before it had those critical manifestations which constitute the disease.

So long ago as 1877, the author of this paper presented to the American Public Health Association, at Chicago, a memorandum as to "*The Sanitation of Individuals with Reference to the Arrest of Infectious Diseases.*" It proposed to deal "with unattacked members of a household in such a way as to render them unsusceptible to the invasion of disease, or so far forestall its attempted derangement as to render it tractable." The idea suggested was "to introduce into the avenues through which contagions chiefly entered, or into the blood on which their first changes are wrought, such substances as will prevent incubation, or enable the blood to resist the changes which are sought to be made, and which constitute the formation of the disease."

Quinine, potassium chloride, and ferrum chloride were among the substances mentioned. The claim was not that of specific action, but that these and other substances could be so introduced into the system as, for several days, to keep up a constant presence about the fauces and in the circulation which would antagonize the processes which infected particles seek to set up, and which constitute the gravity of the disease. These views were the result of closely observed experiments with diphtheria and scarlet fever and intermittent fever, and were well known to families and to physicians in the section in which the practice had been initiated on a scale as large as a few virulent outbreaks in the practice of one individual would permit. When the yellow fever broke out at Memphis, communication was immediately had with Surgeon J. M. Woodworth, of the U. S. Marine Hospital Service, and he expressed his full intention to apply a definite plan of preliminary saturation which had been proposed. These views so impressed Prof. J. L. Cabell, of the University of Virginia, that, in his address before the American Medical Association, in 1878, he made allusion thereto.

A more elaborate outline of evidence was furnished in a paper presented to the American Public Health Association, at Richmond (1878), entitled, "*The Prophylactic Treatment of Individuals as a Means of Preventing Epidemics of Yellow Fever or other Infectious Diseases.*" It was claimed that the most hopeful method of preventing infectious diseases from becoming epidemic was in thus dealing with all exposed persons. In addition to other articles before named, salicylic acid, arsenic, alcohol, sulphurous acid, and some sulphites and chlorides were named.

In view of the more recent reference to the subject, we desire to call the attention of the medical profession to the need of an extended and systematized testing of the methods advised. We already have had as to quinine a prophylaxis of the individual which should make us intensely hopeful as to all infective diseases received from without. Such testing would necessitate the accurate administration of the medicament to the extent of a local presence in the fauces and an ascertainable presence in the blood during the usual period for the incubation of the disease, and even longer where there is continuous exposure. After the first effect has been reached, it is quite surprising how very small doses, if frequent, will maintain the presence in the blood of certain articles. Potassium chloride, for instance, is not only found in the secretions soon after administration, but is easily continued in them by small doses. The same is very true of quinine, of chloride of iron, arsenic, etc. Every advance in our knowledge of the infective diseases points to the development and growth of lower forms of life. We shall yet know how in many cases so to sterilize the human soil that it will refuse to give productivity to that which constitutes the gravity of the disease. If so, we shall have a method for the stamping out of epidemics second to none of those now in more recognized operation.

MEDICAL PROGRESS.

Alcohol in the Treatment of Burns.—Dr. E. Nelasco, in *le Practicien*, gives the following as the method successfully employed in a number of cases of burns. After having bathed the raw surface with alcohol (96 per cent.), he covers it with wadding, which is soaked with alcohol whenever it becomes dry. The pain ceases immediately on the application. In the most unfavorable cases the recovery was prolonged to the eighteenth day, while in the parts in which there was no deep injury, healing, without suppuration, took place on the third day, leaving no trace of the injury. —*L'Union Méd. du Canada*, July, 1883.

Cirrhosis of the Liver of Cardiac Origin.—M. Ch. Sabourin, in an article on this subject, gives the following as the only conclusions that can be drawn: 1. Diseases of the heart may produce a true cirrhosis of the liver. 2. The seat of this cirrhosis is the subhepatic venous region. 3. As sections show, it tends to form complete rings passing around the subhepatic veins—rings which enclose the glandular spaces at the porto-biliary centre. 4. By its histological nature and elementary evolution, it possesses and retains characteristics which permit its ready recognition. 5. It constitutes an important anatomico-pathological element in the history of diseases of the liver; this element gives the peculiar stamp to the hepatic cirrhosis of cardiac origin.—*Revue de Médecine*, July, 1883.

Subcutaneous Ligature of Varicose Veins.—At the meeting of the British Medical Association, recently held in Liverpool, Mr. W. H. Folker read a paper on this subject. Formerly, he adopted the method of treatment by potassa fusa and lime eschar, but at present he only uses the ligature or suture. Either of these, which are applied merely till a clot is produced in the vein, and then removed without completely dividing it, he considers not only unreliable, but dangerous, as the clot might subsequently become loose, and be carried up the vein.

Whatever method is adopted, it is absolutely necessary that a complete division of the vein should be effected; but, that accomplished, he thinks the more formidable operations of slitting up or dissecting out portions of the vein are then quite unnecessary. A hare-lip pin passed under the vein, with silk twisted over it, is effective if allowed to cut its way through; but it is clumsy, and also very uncomfortable to the patient to have three or four needles in his legs, with the cut ends projecting, however carefully they may be dressed. The brooch with pad and screw only serves to stop circulation in the vein till a clot is formed; but it does not sever the vein completely, and is, therefore, not to be depended upon.

The plan which he now proposes to bring before the profession is that of subcutaneous ligature of the vein; it will be found safe, efficacious, and very simple and easy to apply. It is safe; for the ligature is applied with the slightest possible disturbance of the surrounding parts. It is efficacious, as it completely stops all circulation in the vein for ever afterwards; and the operation is extremely simple and easy to be performed.

A very small incision is made on each side of the vein, of the width of a tenotomy-knife. The ligature is then passed under the vein with a curved needle, which is made to enter at one incision, and is brought out at the other and withdrawn, leaving the ligature *under* the vein. The straight instrument, which is just sharp enough to go through fat and cellular tissue, but not sharp enough to endanger a vessel, is passed from one incision to the other between the skin and the vein; it is then threaded with the ligature, and withdrawn. The ligature now encircles the vein, with both its ends through the first incision. It is tied as tightly as possible, and the ends cut off closely. If a spot of blood remain, it is to be sponged away, the skin dried, and the incisions pencilled over with collodion, and the operation is complete.

Of course he does not pretend to say there is anything new in tying a varicose vein subcutaneously, though he wishes to suggest its more general adoption, as being thoroughly effectual; and by using the little instrument devised for the purpose, the operation may be performed in the easiest manner possible, even by any one not much accustomed to operating. There is nothing unsightly for the patient to see; and the part may be easily and comfortably dressed.

This last may be considered by some a trivial matter, but many of the patients will be induced to submit to this, who would be frightened at the idea of a cutting operation.

Mr. J. R. Humphreys (Shrewsbury) said that he had applied the various methods for the relief of varicose veins, and amongst them the method of subcutaneous ligature; but of late he had cut down on the vein, and tied it below and above, about an inch apart, and cut the intermediate portions. He had had some troublesome cases of varicocele which he had readily cured by this means, and had no bad result.—*British Med. Journ.*, August 18, 1883.

Operation for Determining the Sex of an Individual.—In November, 1882, a person, æt. 22, came to Prof. Porro for the purpose of having the sex determined. This person had been brought up from infancy as a girl, but all proclivities and instincts had been masculine. The height of the individual was five feet two and a half inches; weight 130 lbs.; the features masculine, with a few black hairs on the face and upper lip. The thorax was that of a man, the breasts developed similarly to those of a young girl, but the nipple was non-erectile. The abdomen was flat, but the conformation of the pelvis was similar to that of a woman. The arms were those of a man, but the lower limbs of feminine conformation.

There was a penis very slightly prominent; the pudental region, when the legs were brought together, resembled that of a woman. There was a vulva with a slightly developed clitoris, the glans of which extended only six-tenths of an inch beyond the prepuce. At the base of the glans were two folds of mucous membrane resembling labia minora; these being separated, the examiner found a canal about one and six-tenths inch long which extended from the base of the glans to an opening in the median line, about two and two-fifths inches from the anterior margin of the anus. This led to another canal, one and four-fifths inch long, which opened into the bladder.

Two cutaneous folds of larger dimensions than those already mentioned, but parallel to them, were found on either side of the peniform body. They were covered with hairs, and were similar to labia majora. At their upper part, two hard bodies were felt at the ring near the inguinal region, pressure on which caused no painful sensation. Rectal touch gave no evidence of the existence of a prostate, nor was any uterus discovered.

On December 9 Prof. Porro opened the genito-crural fold of the right side, and found that the hard body was the testicle with the epididymis. The spermatic cord was present, and attached to the testicle. A few catgut sutures and a Lister dressing were applied, and five days afterwards the man left the hospital. [This operation is somewhat similar to one reported by Prof. S. D. Gross in The Amer. Journal of the Med. Sciences, Oct. 1852, which was more thorough, however.]—*L'Abeille Méd.*, Aug. 27, 1883.

Action of Lead on the Vagus.—Curci, after some physiological experiments on the subject, states that lead salts have an irritating action on the vagus. They act at the same time on the inhibitory centre of the heart and on the terminal intracardiac branches. Under their influence, the heart-beats diminish in frequency, and become intermittent. The systolic bruit is also diminished in duration while the diastolic bruit is prolonged.—*Gaz. Hebdom.*, Aug. 17, 1883.

Case of Horny Tumor on the Cheek.—At a meeting of the Calcutta Medical Society on July 11th, notes of the following interesting case were read: Bhondu, a fuller, was admitted into the Rai Bareli Sudder Dispensary on the morning of 29th July, 1882, with a peculiar tumor on his left cheek. His previous history is that about eight years ago he first felt a hard, painless swelling come on in his left cheek, just near the angle of the mouth. For the first few months he took no notice of it, simply because it did not trouble him, but after the lapse of some more months, it became double its size and very unsightly. He thereupon consulted a barber-surgeon, who applied some medicine, and a fortnight after its use, a thin layer of skin, as the patient says, peeled off its surface, leaving exposed to view a hard, white swelling like a horn in structure. No medicine had any effect in checking its progress, and four years after it was first noticed, it became about two and a half inches long. He again went to the barber, who sliced off the projecting mass with a razor. He (the patient) could still feel a hard plate sticking as if it were in his cheek. Some time after, it again attained its former size, and he had it again cut off by the barber. The last operation was performed about two years ago. The tumor has now again increased in bulk, and is larger than it ever was before. From the very beginning, it has been perfectly painless, the only source of inconvenience and anxiety being its size and presence on the face.

Present state (at time of admission). There is a pyramidal mass projecting out of the left cheek. It is about three inches in length. The apex is a cut, triangular, uneven surface, about one inch square, having rather a constricted neck. Its thickness is much greater towards the base, which is embedded in the substance of the cheek. On running the finger over the base from within the mouth, a hard substance is felt, as if it were sticking in the cheek. Its circumference is about three inches. Pressure upon the tumor from within or without the mouth does not give any pain, and the whole thing looks exactly like a horn on a man's face.

Treatment.—The tumor was dissected out. It was found to be embedded in the whole thickness of the cheek, and the mucous membrane of the mouth was, in the course of dissection saved with great difficulty. The after-treatment was carbolized lint, and on the 12th August, 1882, fifteen days after the operation, the man was discharged cured, the wound having filled up with granulations.—*Indian Medical Gazette*, August, 1883.

Uraguara.—M. P. Merlini reports several cases in which the tincture of uraguara (*Didinamia angiosperma*) has been successfully used in chronic bronchial and pulmonary diseases. The first patient had symptoms of pulmonary phthisis; after three months and a half of treatment, there was only a slight vesicular murmur. The tincture is prepared from the leaves or from the bark of the root, and is given in doses of gtt.v.-xx three times a day, before meals, in a glass of water. The tincture is well borne by the stomach, and a continuous use during several months produces no digestive troubles. It causes an increase in the appetite and an improvement in general strength. Merlini states that in several cases in which cod-liver oil, iron, lime salts, etc., had given no improvement, he obtained excellent results with the uraguara.—*Progrès Méd.*, August 18, 1883.

Extirpation of the Uterus.—Bölling, of Upsula, reports the case of a woman, æt. 57, upon whom he performed colpo-hysterectomy in July, 1882, on account of cancer. The growth had become attached to the anterior roof of the vagina, and the bladder was torn when the cervix was removed, but was immediately sewed up. The uterus was removed through the posterior part of the vagina. The broad ligaments were separated and ligated, and the ovaries left in the pelvic cavity.

By sutures in the corners the wound was entirely closed with the exception of an opening about as large as a finger, through which a drainage-tube was inserted. The vagina was then tamponed with iodoform gauze, and the patient put to bed. There was no rise of fever.

Recovery went on uninterruptedly, with the exception of a vesico-vaginal fistula, which, however, closed spontaneously in five and a half months, at which time the patient was still free from recurrence of the disease. Examination of the uterus showed that the internal os was involved.—*Centralbl. für Gyänkol.*, Aug. 4, 1883.

The Seat of Urea Formation.—Dr. Shroeder has recently performed some interesting experiments on this subject (*Kleb's Archiv*, t. xv.). He constructed an apparatus by means of which the blood of the animal experimented upon was caused to flow through certain organs, the liver, kidneys, etc. Notwithstanding a continuous circulation of two hours or more through the liver, the blood always contained the same amount of urea at the end of the experiment. The liver is therefore, in Shröder's opinion, the urea forming organ *par excellence.*—*Gaz. Hebdom.*, August 24, 1883.

Precautions for Persons attending Cholera Patients.—The Board of Health and Public Hygiene of the Department of the Seine has issued the following circular, presented by M. Dujardin-Beaumetz: Persons having the care of cholera patients, or who live with them, should observe the following rules: They should neither eat nor drink in the chamber occupied by the infected person. Before eating or drinking, they should rinse out the mouth, and thoroughly wash the hands and forearms with a two per cent. solution of borax. They should bathe the whole body every day with water containing ʒiiss of borax or grs. xv of thymic acid to the half gallon.

Whenever any fecal or vomited matters soil the clothes, they should be immediately washed with a solution containing ʒv of sulphate of copper to the half gallon of water, or with boiling water. When the clothes are extensively soiled, they should be placed in a closed apartment, where ʒijss of sulphur must be burned for every cubic yard. The clothes should remain in this place for twenty-four hours.—*Progrès Méd.*, August 18, 1883.

The Perspiration in Healthy and Nephritic Subjects.—From a number of experiments upon himself and other men, Dr. Janssen, of Leyden, draws the following conclusions:

I. In Healthy Subjects.—1. Vapor of water is continually being exhaled through the skin.

2. During the course of the day, the quantity of vapor of water evaporated varies at different times; it decreases from the early morning till midday, and then rises from that time until evening.

3. These regular variations are independent of the use of solid or fluid food, as well as of the bodily temperature, so long as it remains within normal bounds.

4. The ingestion of food and drink has no influence on the exhalation of vapor of water through the skin.

5. The production of vapor of water rises with increased, and falls with decreased, temperature.

6. The different parts of the body contribute unequally to the amount of perspiration: the arm furnishes, relatively, much more perspiration than the leg.

7. The perspiratory functions are more energetic in males than in females.

II. Perspiration in Nephritic Subjects.—1. Subjects of nephritic disease continually lose considerable quantities of water through the skin.

2. There is no regularity in the quantity of perspiration exhaled.

3. If the parts of the body are œdematous, more water is exhaled than when œdema does not exist.

4. In cases of acute nephritis, and perhaps also in nephritis with shrunken kidneys, but little water is exhaled.

5. In nephritis and in cases of enlarged kidneys, the behavior of the sweat-glands is different. In a case in which there was œdema of the extremities and face, urine small and containing albumen, the perspiration was less than in a healthy person. In a case of diabetes also the amount of water exhaled from the whole arm in an hour only amounted to grm. 0.031, an enormous decrease.

Janssen has been able to find no difference between the varieties of nephritis as to the amount of carbonic acid exhaled from the skin, nor between œdematous and non-œdematous parts in this respect.—*Deuts. Arch. f. klin. Med.*, Bd. xxxiii., Hft. iii. and iv.

THE MEDICAL NEWS.
A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made at the risk of the publishers, by forwarding in REGISTERED letters.

Address, HENRY C. LEA'S SON & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA, PA.

SATURDAY, SEPTEMBER 15, 1883.

THE ORIGIN OF SPECIFIC DISEASES.

IN a recent Address on Pathology, delivered before the British Medical Association, DR. CHARLES CREIGHTON tries to show how certain diseases now recognized as specific, and which he characterizes as autonomous, that is, having a certain existence of their own independent of the normal physiological processes of the living body, may have arisen by a process of evolution from successive gradual changes in these physiological processes. He appears to entirely ignore the germ theory, and, although he starts out with the proposition that disease is only a modification of a healthy state, he becomes confused and obscure as he goes on, and speaks of infections which can exist outside the human body in the sense of diseases, thus confounding the cause with the effect.

He supposes cancer to arise from disordered secretion; tubercle in cattle from disordered nutrition more especially in certain deposits of fat; smallpox to have been originally a non-contagious skin disease of the negro; and yellow fever to be a modification of typhus developed in the slave trade.

This last is an old theory, advocated by a French physician, M. Audouard, to explain the introduction of the disease at Barcelona in 1821, but which has never met with any general acceptance by medical men. Contagious fevers appear in fact to have been of very rare occurrence on the slave ships, the chief source of mortality having been dysentery. Dr. Creighton seems to think, however, that the cause of dysentery in the black is the cause of yellow fever in the white, but this is a mere supposition; and is negatived by the fact that the converse does not hold good, for in epidemics of yellow fever there is no corresponding epidemic of dysentery in the colored population. If the poison of yellow fever can be generated by overcrowding and filth among the blacks, it ought to occur every summer in some of our large cities; which is not the case. Dr. Creighton's speculation as to the origin of smallpox rests on even more slender foundations than the yellow fever theory. The truth is, that all such speculations which ignore the effects of micro-organisms are very much like the celebrated Lyceum debate on the relative priority of the chicken and the egg. Fifty years ago it might have been permissible to write an elaborate treatise to prove that the phenomena of trichinosis were due to the use of beer, and the process of evolution acting on the Germanic race, but such is no longer the case.

We can understand the possibility of the production of disease in man by parasitic organisms; we can also readily conceive that by the process of evolution either the powers of these organisms may be changed, or the tissues of the human body may be rendered more or less susceptible to their effects, but we have no evidence in favor of the spontaneous generation of such organisms.

It is a good rule in investigating contagious and epidemic diseases to determine first the influence which known and existing circumstances have on their rise and development, and to make use of unproved and unprovable hypotheses only in regard to the unexplainable residuum.

If, for example, we wish to compare the theory that smallpox is due to a parasitic organism, which either has, or at all events originally had, a separate and independent existence, with the theory that smallpox is due to the grafting of particles of living matter from one living body to another, the first question which arises with regard to the latter supposition is, how long can particles of living matter, not independent organisms, retain their vitality when separated from the human body. This is a question which is a legitimate subject for experiment, but so far as we now know such survival of vitality is limited to a few hours. It has been determined, however, that the particles which have the power of producing smallpox or scarlet fever retain that power for weeks and months. By what law of evolution is it conceivable that this power of retention of vitality should be developed in connective-tissue cells?

It appears to us much wiser to investigate the causes of disease, organic and inorganic, which are now acting on man, than to speculate about possible causes of several thousand years ago. Such a statement as that "a mere condition or state of the ruminant body can be abstracted, as it were, from all other ruminant conditions, and made to live in another body," is very illy calculated to stimulate inquiry as compared with Koch's definite statements of the presence of a peculiar form of bacillus in bovine tuberculosis. Sydenham's definition of a specific disease as "one that takes its rise in a specific exaltation or specification of some juice of the body," which Dr. Creighton says expresses his meaning, reads to us much like the celebrated explanation that the narcotic effects of opium are due to a certain sleep-making power which it possesses.

We do not wish to be understood as advocating the germ theory or the graft theory of the causation of specific diseases, but only as urging that these theories are much more worthy of consideration than that of specific conditions or states of the body, for the reason that they are susceptible of investigation by experimental methods, while the latter is not.

THE PICRIC ACID AND OTHER TESTS FOR ALBUMEN.

The profession is much indebted to Dr. George Johnson for recalling attention to picric acid as a delicate test for albumen in urine. Attention was first called to it about ten years ago, when it was recommended that into a saturated solution in a test-tube the suspected urine be allowed to fall, drop at a time. Should albumen be present in sufficient quantity, a distinct cloud is observed to follow each drop of urine as it descends through the picric solution.

As thus applied, the picric acid is not a delicate test for albumen. Nor is it when simply mixed with urine; but in the following modified form it is by far the most delicate and convenient test we have handled. Dr. Johnson recommends that a saturated solution, made with boiling water, be allowed to flow gently from a pipette upon some of the suspected urine in an inclined test-tube, just as in the nitric acid test the acid is overlaid by the urine. The order is here reversed, because the picric acid solution is lighter than most urines. If there is the least albumen present, a delicate but sharply distinct white line appears at the border between the two fluids. Even more care is required in carrying out this process than with the nitric acid test, since the two solutions approach each other more nearly in specific gravity, and, therefore, diffuse more readily. At the same time, the white line remains a longer time, because the precipitated albumen is not dissolved so quickly by the picric acid as it is by the nitric.

We have for some time been in the habit of testing each specimen of urine we have been called upon to examine, by heat, by nitric acid, by the acidulated brine suggested by Dr. Roberts—made by adding an ounce of hydrochloric acid to a pint of water, saturating with common salt and filtering —and by the picric acid solution. As the result of these experiments, we have found that quantities of albumen, so small as to escape detection by the nitric acid and acidulated brine, can be detected by heat and subsequent acidulation—particularly after setting aside for a few hours, when the doubt as to a diminished transparency is often settled by the presence of a delicate sediment, not soluble by heat. But we have further learned that a quantity of albumen which would escape detection by the latter method can be demonstrated without doubt by overlaying the urine by the picric acid solution.

As to the relative value of the nitric acid and the acidulated brine, we believe the latter is a trifle more delicate, partly because the color-line, which always forms at the junction of the acid and urine, is never so marked when the brine is used. And when we consider that the salt solution is very much more satisfactory to work with because of its comparatively non-caustic properties, it is greatly to be preferred, and should be always used instead of the pure acid.

We have heretofore continued to use the nitric acid, as well as the boiling with subsequent acidulation, although the latter is far more delicate than the former for small quantities of albumen, because it is well known that sometimes, when *comparatively large amounts* of albumen are present, it fails to be thrown down by heat; or only a trace appears, the remainder, often a considerable amount, remaining in solution. And although this acid-albumen may be made to show itself by working to and fro with larger quantities of acid and reapplying heat, yet it never fails to appear by underlaying with nitric acid, and, of course, with the acidulated brine, so that the two methods are a check upon each other. We shall never forget the look of dismay upon the face of a poor woman who had been in the habit of testing the urine of her daughter, and who had detected but a trace of albumen for some weeks, and sometimes none at all, when upon our adding a little more nitric acid, and again boiling some of the same specimen which she had herself tested, down came a copious precipitate of albumen.

This source of error, so far as we know, is also avoided by the picric acid test, so that, for large or small quantities of albumen, it becomes the most delicate test easily available. Lest it should be thought that the precipitate represents some other form of albumen than the serum albumen found in deranged renal circulation, we would state that not only have we found numerous specimens of urine in which there was no response whatever to picric acid, but in every instance in which the reaction occurred, the urine was from cases where, on account of irritation of the genito-urinary passages. it was reasonable that albumen should be present; so that we are in hearty accord with Dr. Johnson that it is a delicate test for serum-albumen only. In the way of objection to the picric-acid test this alone can be said: When working with urines of low specific gravity, it is difficult to overlay them with the solution of picric acid, because of such low specific gravity, in consequence of which the two fluids diffuse very rapidly. And again, to some the vivid yellow stain which it imparts to the hands may be an objection.

Other test solutions for albumen to which attention has recently been drawn are (1) saturated solution of ferrocyanide of potassium with free acidulation by citric acid, suggested by Dr. Pavy; (2) solution of potassio-mercuric iodide after acidulation with acetic acid (Tauret), or by citric acid (Stephen); (3) acidified solution of potassio-mercuric iodocyanide, and (4) acidulated solution of sodium tungstate. The last two were suggested by Dr. George Oliver in the *Lancet,* February 3, 1883. The solution of ferrocyanide of potassium is less delicate than the picric acid, but the potassio-mercuric iodide is equally sensitive. The acidulated solution of potassio-mercuric iodocyanide is also delicate, but troublesome to prepare. In a limited experience, we have not found the sodium tungstate solution suggested by Dr. Oliver, as delicate. It is made by mixing equal parts of a saturated solution of the tungstate salt, saturated solution of citric acid, and water; and as thus prepared it is colorless and of a higher specific gravity than most urines. The potassio-mercuric iodide may be preferred by some on account of its absence of color, but the picric acid will always recommend itself by reason of its easy preparation and simplicity, no special preparation, and no acidulation by other acid being required. We are in the habit of preparing and keeping a solution in an ordinary test-tube.

One most important precaution must be observed in testing for small quantities of albumen, by whatever reagent—*always work with a transparent urine.* If a turbidity cannot be filtered out in the ordinary way, add solution of potash, and warm before filtering.

With these more modern additions to our qualitative tests for albumen, it would seem that in this department of urinary chemistry all has been attained that can be desired.

LITHOLAPAXY.

It is not a little surprising that Bigelow's American operation has found its chief practical welcome abroad, as shown by the *résumé* of 590 operations, given in a paper by Desnos, in a late number of the *Rèvue de Chirurgie.* Of the 46 operators quoted, Guyon leads with 226 operations, and Sir Henry Thompson follows with 101, together counting more than fifty-five per cent. of the total number. Only nine other operators have done it in ten or more cases. Of these, Bigelow himself has done the most (forty-five), and Van Buren and Keyes follow with thirty-three. Scarcely a single American case is quoted outside of Boston and New York. Yet its success has been so remarkable, even from the single standpoint of the mortality, to say nothing of rapidity and comfort of the cures, that it ought to be at present the operation *par excellence.* Yet the surgeons of the Middle, Southern, and Western States seem for the most part to have ignored it. Guyon has obtained cures in 94.7 per cent., as against 91.8 by ordinary lithotrity, in spite of the fact that he has treated stones of even five and one-half centimetres (two and one-eighth inches) in diameter. The duration of treatment he has brought down from forty-seven days in lithotrity to seventeen days in litholapaxy, while the occurrence of fever and other accidents has variously diminished from four to thirtyfold. In Sir Henry Thompson's and Van Buren and Keyes' hands, the recoveries were ninety-seven per cent., and in Bigelow's, about ninety-six per cent. Of the whole number, six per cent. died, as against about eleven per cent. by ordinary lithotrity.

Desnos gives a history of the steps by which this "complete revolution," as he well terms it, has been attained. Beginning with Heurteloup in 1829, Cornay in 1843 (who devised an aspirator with an air-pump), Crampton, and Amussat, each added somewhat, the latter, in 1853, even proposing the crushing of the stone at a single sitting. But under the shadow of the great names of Nélaton and Thompson, lithotrity for twenty years was limited to short and frequent sittings, leaving a large number of sharp, angular fragments, sure to do mischief to an already inflamed and sensitive bladder.

Meantime, under the lead of Otis, investigation had developed the fact that the normal urethra was larger than had been believed, and resting largely upon this fact, Bigelow devised most happily his new operation, an operation which he and others have modified and improved in detail, but the principle of which remains intact—a laurel well deserved. Once that instruments of large calibre could be introduced into the bladder, a stone, broken into numerous small fragments, or better still, as Desnos insists, almost into sand, could be sucked out at a single sitting, and the bladder relieved at once. One other step was needed, and that Bigelow boldly tried and proved it feasible—anæsthesia. This rendered possible a prolonged sitting, with repeated crushings and aspirations. There is now no possible doubt that a prolonged sitting and repeated mechanical operations, which get rid of the stone at once, are less dangerous to the bladder than frequent short sittings, which leave numerous fragments. Indeed, it is even possible that we have gone too far in prolonging these operations to two or three hours, or even longer, and that a fragment or two may be left for removal at a later sitting rather than prolong the operation to such an extent as to injure the patient either by the prolonged anæsthesia or by too long-continued manipulation. Guyon's sittings averaged only twenty-three and a half minutes, and hardly ever lasted an hour. The same may also be said of the size of the evacuator. While the largest possible instrument is theoretically the best, those of somewhat smaller size present a facility of introduction and safety in manipulation that recommend them greatly; even a No. 16 of the French scale has served an excellent purpose. Especially is this true if the crushing be effectually done first.

The operation is as yet in its infancy; but it is a lusty infant. Improvements, mechanical and manipulative, are constant. We are learning its limits and its capacities. It will be a shame if it should find its home in Europe rather than in America, and receive its improvements more from foreigners than its countrymen. Sir Henry Thompson gave it a rather frigid reception at first, but, as his figures show, he is now its warm friend, and his name alone is a tower of strength. We bespeak for the method a more general trial. How many Philadelphia surgeons have tried it? How many west of the Alleghanies? How many south of the Ohio?

TRAINED NURSES.

Until birth, sickness, and death pass away nurses will remain a necessity. The fact being so, the quality of the nurses to be had is no longer a matter of indifference, but of profound interest to the sick, and of almost equal importance to the well; for these last have deeply at heart the recovery of their dearest ones, and it is but a question of time when they themselves will be numbered among the sufferers.

The credit of first establishing training schools for nurses has generally been given to Pastor Theodore Fliedner, of Kaiserswerth on the Rhine, in 1836, or to Miss Florence Nightingale, as a result of her experience during the Crimean War in 1854. But the fact is, that the Philadelphia Lying-in Charity began its efforts in this good cause as early as 1828, under the late Dr. Warrington, and subsequently under Dr. Ellwood Wilson, who also gave there in 1856 the first public gynecological clinic.

And now comes another plea from this city for more and better trained nurses. The Nestor of the American profession in another column makes an urgent and timely appeal for more widely diffused opportunities for such training. Our chief cities, Philadelphia, New York, Boston, Washington, New Haven, Chicago, San Francisco, etc., have all well-established schools for this purpose, but Prof. Gross, with his large-hearted sympathies, makes a strong plea for the towns and villages of the *country*.

Sickness knows no latitude. It has no geographical limitations. It is not metropolitan in its manifestations. Farmers and laborers suffer from it as much as the inhabitants of our cities. Indeed, in view of the far larger number of the rural population and their lessened facilities for obtaining nurses, and the infrequent visits of their doctor, often miles away from their homes, country-folk need good nurses far more even than city-folk.

The knowledge nurses need does not "come by nature." The "knack" for nursing is more or less an inborn quality, but "knack" plus training is quadrupled power. Some such plan as is so admirably sketched by Dr. Gross is entirely feasible, and if realized would supply in many a country town and neighborhood a pressing want and save many a life.

Moreover, we are glad to see another point in Dr. Gross' scheme—a point that should be thought over in our cities especially—that such instruction be given to *men* as well as women. As to men, it is a fact that there are no "trained" male nurses in the same technical sense as we speak of trained female nurses. A few good male nurses there are, trained in the school of experience—the same school that existed for women long before the Philadelphia Lying-in-Charity and the Kaiserswerth school were thought of. But that is not "training." There ought to be for male nurses the same opportunities that exist for women.

We trust, in the contemplated training school at the Philadelphia Hospital, that adequate provision will be made for giving men equally full and complete instruction.

In conclusion we urge two points: First, let the press, medical and secular, as is requested by the distinguished author, call wide attention to the subject and so arouse the interest, both of the profession and the public, to an urgent need. Secondly, let us hear speedily that the plan has been actually tried in some enterprising rural neighborhood. Let us hear of the methods adopted, the modifications found necessary, and the results obtained.

NOISE NUISANCE.

To the sick and convalescent, and to "nervous people"—a class rapidly increasing in number with the progress of our civilization—street noise is an intolerable nuisance which, in some cases, may result in positive injury, and is a penalty paid for living in the city. Many of these noises are, in a degree, the necessary concomitants of traffic and manufacture, and are, therefore, the results of useful occupation; others are inheritances from by-gone days, and have long since survived the period of their utility. Of the latter we may mention, as conspicuous examples, the church bell and the factory whistle, both of which have been entirely superseded in their useful purpose ever since the introduction of watches into universal use.

In Great Britain the factory whistle has been controlled and ameliorated by Act of Parliament, and in this country the church bell is likely to be regulated by the courts. Indeed, the Supreme Court of Pennsylvania, in 1877, declared that the noise produced by the ringing of the chime of bells in a certain church in Philadelphia to be a nuisance to be abated, and it enjoined their ringing, except for certain services on Sunday, when it is permitted for five minutes preceding these services. In New York the ringing of the bell of St. George's Church has caused considerable annoyance to the residents in the neighborhood of Stuyvesant Park, who have recently brought the matter to the attention of the Board of Health, and, if necessary for its abatement, we are informed, will carry it to the courts, which, following the tendency of all recent decisions both in this country and in England concerning such nuisances, will, doubtless, grant equitable relief.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF VIRGINIA.

Fourteenth Annual Meeting, held at Rockbridge Alum Springs, September 4, 5, 6, and 7, 1883.

(Specially reported for THE MEDICAL NEWS.)

SEPTEMBER 4TH, FIRST DAY.

EVENING SESSION.

THE Fourteenth Annual Session of the Medical Society of Virginia, convened at Rockbridge Alum Springs, Va., at 8.30 P.M. This renowned health and summer pleasure resort was selected as the place for the present meeting, in acceptance of an invitation from Col. Frederick Effinger, the President of the Springs Company. The attendance was about one hundred physicians from this State, besides some distinguished gentlemen from other States, prominent among the visitors being Drs. L. McLane Tiffany, Dean of the University of Maryland, and John N. McKenzie, of Baltimore, and Julian J. Chisolm, of Baltimore.

A band of music enlivened the occasion of the assembling, and many ladies, besides hosts of the male guests of the Springs' Hotel favored the Society by their attendance.

DR. WM. D. COOPER, of Morrisville, Va., PRESIDENT of the Society, occupied the Chair.

After prayer by Rev. Dr. J. J. Lafferty, the next order of business was announced to be the

ANNUAL ADDRESS TO THE PUBLIC AND PROFESSION,

by DR. J. E. CHANCELLOR, of the University of Virginia. After stating that, by the request of the manager of the Springs, and as a former resident physician on these grounds, he welcomed the Society and urged the members to enjoy the pleasures which might be found here. Dr. Chancellor then announced as the subject of his address,

MINERAL WATERS.

He reviewed the history of mineral water from the earliest times down to the present, and then after defining what a mineral water is, he proceeded with an exhaustive discourse upon the formation of such waters; their chemistry and composition, the geological character of the soil which produces them, where they are likely to be found, and their classification, and their importance as medicinal agents, closing his address by a comparison between natural and artificial mineral waters, and demonstrating the fact that the latter can never equal or take the place of the former. The address was warmly received by both the public and profession, and is an important contribution to the literature of the subject.

After some formal business, the Society adjourned.

WEDNESDAY, SEPTEMBER 5TH, SECOND DAY.

MORNING SESSION.

After the meeting had been called to order at 10 A.M., and the minutes of yesterday were read and approved, DR. G. WM. POLLARD, of Aylett's, Va., Acting Chairman of the Committee on Applicants for Fellowship, presented his report. Some thirty-eight or forty new members joined during the session.

THE PRESIDENT next appointed thirteen Fellows, representing different sections of the State, a committee to *nominate officers* for the ensuing term.

At the hour of 11 A.M., the special order of business being the

PRESIDENT'S ADDRESS,

DR. WM. D. COOPER proceeded to deliver it—after inviting Vice-President, Dr. Meade C. Kemper, of Goshen, Va., to assume the chair for the time. His subject was the *Individual Rights of Physicians, and the Limited Protection afforded them by our State Laws, with Suggestions as to Some Action of Redress.* It was an excellent address, clearly defining the rights of doctors to claim special legislation to enable them to perfect themselves in scientific studies, so as to be more servicable to the people, while at the same time they may protect themselves against the encroachment of quackery, charlatanry, etc. The power of thorough organization and determined effort were well pointed out.

The next order of business was the report on advances in different departments of medicine.

REPORT ON ADVANCES IN ANATOMY AND PHYSIOLOGY.

DR. JOHN R. WHEAT, of Richmond, Va., Reporter. This paper showed careful study of the subject in hand.

REPORT ON ADVANCES IN CHEMISTRY, PHARMACY, MATERIA MEDICA, AND THERAPEUTICS.

Honorary Fellow and ex-President DR. A. M. FAUNTLEROY, of Staunton, Va., Reporter. Chemistry, since Sertürner, over fifty years ago, announced the discovery of morphia, has played an important *rôle* in medical progress. In the last few years, *actinium* has been separated in the metallic state. *Liquefaction of ozone* has been accomplished by compressing ozone in oxygen, and the indigo-blue drops have been preserved for nearly thirty minutes. The probable existence of active allotropic nitrogen was referred to. Ammonia from the atmosphere may be obtained by deoxidizing the air by coal dust, in the presence of watery vapor, at red heat. Common salt is put in the furnace with the coal; liberated chlorine combines with the nascent ammonia, forming ammonium chloride. Artificial indigo, by synthesis from a benzine nucleus, is an industrial chemical triumph, for colorless propiolic acid, when treated with a reducing agent, yields indigo blue.

Apomorphia, the reporter has repeatedly witnessed as an abortive of epileptic seizures, and as a calmative in cases of acute mania. This suggestion is valuable, since it comes from a reporter who has had years of experience with brain and nervous disorders, as former medical superintendent of the largest insane asylum in the State. He recommends it to be used hypodermically. The conversion of morphia into codeine, by chemical processes, was referred to, and the phenyl character of morphine, he thought, seemed established. Under the heading of constitution of atropine and its derivative products, tropic acid, tropine, and homatropine, were mentioned, and the mydriatic effects of the latter agent referred to. Hyoscine was spoken of therapeutically as a surer agent than atropia. It is also valuable in whooping-cough, asthma, and epilepsy. The alkaloids of cinchona, and its derivative products, were next considered. Chinoline salicylate and tartrate were mentioned chemically, and the synthesis of thymol and resorcin were the last reference made to the chemical department of the subject.

Glucose as an excipient of pill masses was specially commended, as well as nitre tablets for asthma and insomnia. Solution of morphia in boiling water for hypodermic use, was the next topic. Compressed disks for hypodermic use were mentioned. Colorless tincture of iodine was referred to cosmetically. Several agents were referred to as deodorizers of iodoform, none of which was so highly commended as Tonka bean. The use of chloral hydrate as a vesicant —long ago suggested—is now put forth as an established success. The chloral is sprinkled on adhesive plaster, and applied to the flesh while warm. In about ten minutes the part is free from pain, but blistered as effectually as if by fly-blister.

Jamaica dogwood blunts pain and promotes sleep, and was recommended as particularly valuable where opium cannot be used. Dr. Fauntleroy has given it successfully in facial neuralgia. It is best given with milk. Rhamnus purshiana, Cascara sagrada, as a tonic aperient for infantile indigestions, etc., were referred to. Convallaria maialis as a cardiac stimulant, and its therapeutical application as the rational outcome of its physiological action, were referred to. It is considered perfectly safe.

REPORT ON ADVANCES IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

DR. M. G. ELLZEY, of Washington, D. C., Reporter, stated that he had assigned the report on Diseases of Children to Dr. Wm. H. Coggeshall, of Richmond, reserving the other two branches of his subject for himself.

Obstetrics.—He said that the advanced state of the science of obstetrics precludes the expectation of brilliant and revolutionary advances. There are perhaps no advances more important than the general observance of the principles of the Listerian surgery in obstetric practice, and the general recognition of the scientific validity of the so-called germ theory of disease. Among the menacing perils of child-birth, eclampsia, post-partum hemorrhage, and placenta prævia still stand forth formidably prominent. The possibility of the production of embolus by styptics—especially preparations of iron thrown into the uterine cavity — was referred to. The abuse of forceps was strongly condemned. No man has a right to terminate a natural labor by force, and whosoever uses forceps to gain time for himself is guilty of a criminal assault.

Diseases of Women.—The recent activity of gynecologists has been so great that it seems hard to select particular advances as worthy of the particular attention of the general practitioner. The reporter strongly condemned the abuse of pessaries, and the making of vaginal explorations of married and unmarried females upon trivial grounds, and protested against the growth of pretended specialism in practice, as in many cases a mere bold system of advertising quackery; condemning also promiscuous resort of women of all ages and ranks to hospitals and specialists for every real or fancied ailment, for the diagnosis and treatment of which every reputable practitioner is, or ought to be, perfectly competent. The reporter dwelt earnestly upon the deplorable results of the abuses which, it is much to be feared, are gradually becoming to be tolerated in medical circles, in the general treatment of uterine disorders.

DR. WM. H. COGGESHALL, of Richmond, Va., read the report on

ADVANCES IN DISEASES OF CHILDREN,

in the course of which he made special mention of congenital phimosis, and its treatment. He made protest against the indiscriminate performance of circumcision in cases where true stenosis is absent, as in many such instances the condition may be relieved by the employment of a little dexterity on the part of the surgeon. He also advised against the too common employment of chloroform in convulsions, and referred to the favorable mention by later writers of nitrite of amyl inhalations for the relief of this affection. Reference was made to the remarkably successful results obtained last year by Dr. Macguire, of New York, in the treatment of cancrum oris by subnitrate of bismuth. He gave the treatment of the commoner forms of children's diseases as employed in the New York hospitals for children, closing with a strong recommendation of the fluid extract of ergot for employment as a systemic treatment in pertussis, from his personal experience.

After the reports had been read, DR. GABRIEL MCDONALD, of Union, W. Va., expressed the opinion that Dr. Ellzey had given a too narrow range to the use of the forceps. In natural labor, Dr. McDonald maintains, when everything is all right as to dilatability of os and position of head, relative sizes of mother's parts, etc., and the pains are effecting no good, he applies the forceps. He thinks it cruel to let the mother suffer so long when she can be relieved by the instruments.

DR. HUME FIELD, of San Marino, Va., asked if he gave chloroform?

DR. MCDONALD replied that he first applied the forceps, then chloroformed, and then delivered.

AFTERNOON SESSION.

The afternoon session was entirely devoted to the election of

OFFICERS FOR THE ENSUING YEAR,

which resulted as follows:

President.—J. Edgar Chancellor, M.D., of Charlottesville.

Vice-Presidents.—Drs. S. B. Morrison, of Brownsburg; P. K. Graybill, of Amsterdam; Bradford Brown, of Alexandria; Samuel K. Jackson, of Norfolk; J. M. Estill, of Tazewell C. H., and Thos. J. Pretlow, of Jerusalem.

Recording Secretary.—Dr. Robert G. Cabell, Jr., ot Richmond.

Corresponding Secretary.—Dr. Hugh M. Taylor, of Richmond.

Treasurer.—Dr. Richard T. Styll, of Richmond.

Executive Committee.—Drs. W. W. Parker, of Richmond, Chairman, and Honorary Fellows, Harvey Black, F. D. Cunningham, J. Herbert Claiborne, and Samuel C. Gleaves.

Committee on Nominations.—Drs. Geo. Wm. Pollard, of Aylett's; Lewis Wheat, J. Philip Slaughter, Wm. D. Hooper, and Hugh T. Nelson.

Committee on Publications: Drs. E. T. Robinson, C. W. P. Brock, and George Ross, all of Richmond.

Evening Session.

Dr. Thos. J. Riddell, of Richmond, Va., moved that the Committee on Publications be instructed to have the forthcoming volume of *Transactions* published separately from any medical journal.

Dr. L. B. Edwards, in seconding the motion, took occasion to speak commendably of the *Atlantic Journal of Medicine*, edited by two members of this Society. Carried.

Under the call for scientific papers, etc., Dr. Thos. H. Howard, of Floyd C. H., exhibited a vial containing

ELEVEN HUNDRED FRAGMENTS OF BONES WHICH HE HAD REMOVED FROM THE EAR

of a woman aged 46 years. She had dreamed some years before that when eleven hundred pieces were removed, she would pass no more fragments. He thought it probable that they were the result of a fracture of the external plate of the skull. He stated that the time occupied in removing the fragments was four years.

The general sentiment of members of the Society who examined the fragments was that many of them were not bones belonging to the human race, and that it was a case of deception by a hysterical patient.

Dr. M. G. Ellzey, of Washington, D.C., presented a volunteer paper on the

THERAPEUTIC VALUE OF THE RAWLEY SPRINGS, VA.

He stated that the Rawley water is an alkaline chalybeate, the iron existing as carbonate of the protoxide, held in perfect solution by excess of carbonic acid, with which the water is supersaturated as it escapes at the fountain. No other water containing iron in this form is known elsewhere in America; but the Rawley water is nearly identical with the celebrated waters of Spa, Schwalbach, and Tunbridge Wells. An analysis of the water by Prof. J. W. Mallet was given, and from the analysis the therapeutic uses of the water may be deduced. The springs are delightfully situated in the midst of the North Mountains, near Harrisonburg, in Rockingham County, Va. The summer climate of the Appalachian hills of Virginia is nowhere surpassed in the entire world. Rawley water is a prompt and most efficient diuretic, closely resembling in the character of its alkaline ingredients the celebrated Buffalo lithia water. From its supersaturation with carbonic acid, it acts like champagne in quieting the vomitings of hysteria, pregnancy, and chronic debauch, and for anæmia and impoverishment of the blood, from whatever cause, in all ages and both sexes, it surpasses in efficacy every preparation of the apothecary.

Dr. L. B. Edwards moved to refer all papers thus far read to the Committee on Publication. Carried.

Adjourned.

Thursday, September 6th, Third Day.

Morning Session.

After the routine work of registering, reading minutes of the preceding day, etc., invitations to places in which to hold the next annual session were presented.

On motion of Dr. W. W. Parker, Rawley Springs, Va., was selected as the

PLACE OF THE NEXT ANNUAL MEETING,

in acceptance of the invitation from the Springs Company, who promise to make no hotel charge to doctors and fraternal delegates who may visit the session.

THE TREASURER'S REPORT.

The Treasurer, Dr. L. B. Edwards, presented his report, which showed a balance of $39 to the Society's credit, and without any outstanding indebtedness. Upon his motion, an auditing committee was appointed by the President, to examine into his accounts and report as early as practicable.

THE REPORT OF THE RECORDING SECRETARY.

Dr. Edwards, as the retiring Recording Secretary, also presented a report, showing that with all the resignations, deaths, members dropped from register, etc., the total membership this year had increased to over 450.

Under calls for papers from fraternal delegates, Dr. Julian J. Chisolm, of Baltimore, fraternal delegate from the Medico-Chirurgical Faculty of Maryland, read one on

HOW TO REMOVE FOREIGN BODIES FROM THE EAR.

He alluded to a common error of belief among the laity, that the ear opens directly into the brain. He mentioned a large number of the foreign bodies that may enter the ear cavity, and described the form of the cavity itself. After suggesting that the physician should always examine for himself to see that a foreign body is really in the ear, and to discover its nature, he referred to the method of examining the cavity by means of a speculum, a reflecting mirror, and a good light, etc., he cautioned against mistaking certain natural conformations for foreign bodies. He then remarked that, usually speaking, certain foreign bodies may remain indefinitely in the ear without injury, and in many cases without inconvenience. To remove an insect, necessarily an air-breathing animal, he recommended to drop in the ear some bland olive oil, which speedily destroys its life, and to follow this up by the use of the ear-syringe with warm water, and the foreign body will soon be washed out. He cautioned against the use of forceps by the inexperienced physician. The true object of his paper was to urge upon physicians the use of the ear-syringe, and a stream of warm water as the all sufficient means for removing foreign bodies from the auditory meatus. "I have never seen a case of foreign body in the ear, not tampered with by others, that I have failed to extract by the syringe." It is in the *persistent* use of this simple and innocent means that the object is finally attained. The syringe should hold from one to two ounces, and be easily worked by one hand. If the foreign body be vegetable in kind, use alcohol instead of water, as alcohol has the power of shrinking vegetable matter swollen by moisture. First, cleanse the ear of all purulent secretions, then fill the aural passage with alcohol, inserting a plug of cotton at the external meatus to prevent its escape. It can do no harm to let it remain there all night. After the soft seed in the ear has been shrunken by soaking in alcohol, its removal by the stream of water will be much expedited. When the necessity arises for the removal of a foreign body, and when these means fail of success, it is safer to send the patient to a specialist who is at least apt to be more dextrous in the use of ear instruments than the general practitioner.

Dr. J. St. Pierre Gibson, of Staunton, Va., exhibited

SUSPENSORY-EXTENSION SPLINTS

for fractures of the upper and lower extremities, illustrating their application by "putting up" a man who acted as a patient. The name of the splints indicates the principles upon which they act.

PLASTIC SURGERY OF THE FACE.

Dr. L. McLane Tiffany, a delegate from the Medical and Chirurgical Faculty of Maryland, presented a paper on this subject. He made no attempt to treat the subject exhaustively, but considered the general principles only. The subject was divided into three heads: 1st. Measures for the restoration of parts congenitally at fault, either by excess or deficiency. 2d. Measures for the restoration of parts deficient in consequence of accident or disease. 3d. Measures for the correction of deformity due to cicatricial contraction, a class usually associated with the preceding. The first class differed from the others in several respects, principally because the edges of the deficiency were healthy, and because similar deformities being often seen, opportunity was afforded for perfecting operative measures. The latter two classes comprised cases in which much scar-tissue was an essential element, and differed greatly the one from the other in locality and shape, similar lesions being very rarely seen. The anatomical composition of the face was alluded to, attention being directed to the great mobility of the features.

To remedy a deficiency comprised,

1. Obtaining a piece of tissue to fill the vacancy and preparing its bed.
2. Putting it in position and nourishing it.
3. Filling the vacancy resulting from transfer.
4. Ultimate result as regards usefulness and appearance. Skin similar to lost skin should be always sought for; scar-tissue was to be rigorously excluded, and a flap taken much larger than the space to be filled. Primary union was to be attempted; this failing, union by granulation was to be sought for. Incisions should follow natural furrows, and be out of sight when possible. The flap was to have a broad pedicle without twisting if possible. Packard's suggestion of cutting skin obliquely was referred to favorably. Hemorrhage was to be arrested by hot water and pressure. Granulating surfaces were to be dressed with iodoform and cotton. Quill suture is to be used, passed very deeply, and edges lightly held together by fine wire. Operations should be preceded by an injection of morphia under the skin. Preparatory treatment is generally required.

In operations about the mouth (inside), the patient should lie supine, the face towards a window, horizontal, and the thorax projecting beyond the table supported by assistants at each shoulder, so as to allow the blood to flow from the mouth and not towards the larynx.

DEFLECTION OF THE NASAL SEPTUM AND ITS TREATMENT.

Dr. John N. Mackenzie, a delegate from the Medico-Chirurgical Faculty of Maryland, of Baltimore, after some preliminary remarks on nasal obstruction, and the unsatisfactory manner in which the subject of deflection of the septum had been heretofore treated, proceeded to comment on the frequency of the deformity, the dependence of the form of the external nose upon corresponding peculiarities in the septum, and the influence of national custom in the production of asymmetrical conditions of the cartilage. Deflection is most frequently observed in youth and manhood, is more common in males, and occurs as the result of the changes in the skeleton of the face that accompany the processes of old age. Attention was called to an inherited proclivity to deflection. The deflection may be congenital or acquired; in the latter case it may result from traumatism, or occur as the sequel of a pathological process. He laid special stress upon asymmetrical conditions of the nasal fossæ as a cause of septal deflection, and the possibility of the occurrence of the accident during difficult parturition. The frequent introduction of the finger into the nose, and the cleansing of the organ with the hand were next commented on. Tumors of the nasal and accessory cavities, hypertrophied states of the turbinated bodies, etc., diathetic diseases (rickets, syphilis, osteomalacia, etc.) were also given as causes of deflection, and as a matter of historical interest, the theories of Quelmalzius were referred to. Dr. Mackenzie then gave a detailed and minute account of the anatomical part of his subject, and a description of the different varieties of the malformation based upon his anatomical and clinical observation. He insisted upon the influence of the deformity in the production of throat and middle-ear disease, and indicated the pathological processes which follow as the natural results of the deflection. In connection with this part of the subject, he called attention *to the production of throat and aural disease through the reflex agency of the vaso-motor and trophic nerves*, the primary irritation originating in the turbinated tissues of the nose, and probably from the reflex sensitive area which he had shown to exist in these organs. Passing from diagnosis to treatment, the rational management of the case will vary with the nature and situation of the deflection. The operations with the galvano-cautery, knife, snare, resection, Adams' operation and its modification, the procedure of Blandin, the removal of portions of the septum with the revolving burr of the dental engine and the metacarpal saw, and the suggestion of Dr. Delavan to remove the middle turbinated bone of the *unobstructed nostril* were commented upon, and their relative merits discussed. The operation generally known as "Steele's," viz., triangular division of the cartilage, Dr. Mackenzie showed to have been performed by Dr. Jas. Bolton, of Richmond, eleven years before the appearance of Steele's article. He thought, therefore, that the operation should be known as "Bolton's," and Steele's procedure as a modification of the Bolton operation. To retain the septum in position after operation, Dr. Mackenzie suggested *the use of rubber bags* introduced into the nostrils and inflated, as less liable than other forms of plugs to produce irritation, and as a means of securing uniform pressure. These bags can be mounted on a central canula, after the manner of the well-known rubber tampon for epistaxis. In certain cases of deflection of the bony septum, he recommended as a substitute for operation on the septum itself, *removal of the turbinated bone of the obstructed nostril*, and related a case where he had successfully performed the operation.

A vote of thanks was given to each of the three visiting delegates for their instructive papers, copies of which were requested for publication.

Dr. Joseph A. White, of Richmond, Va., exhibited some *Instruments for Use in Deflected Nasal Septum;* also a specimen of a *Foreign Body Removed from a Patient's Nose.*

The Auditing Committee reported that the

ACCOUNTS OF THE TREASURER

were correct, and upon their motion $25 were voted to reimburse, in part, Dr. Edwards for advances he has made for the Society's interests.

After the installation of the newly elected officers, Dr. Samuel K. Jackson, of Norfolk, Va., read his

REPORT ON PRACTICE.

After alluding to the reproach "That there is so little certainty in the practice of medicine as to allow the proverbial differences of opinion between practitioners," he announced as the subject of his paper, "The advances that have been made towards securing a true scientific basis."

Though Prof. Huxley has dated the rise of medicine back through some eighty generations, scientific medicine can hardly be traced further back than the discovery of oxygen. This is the true era, which occurred but a little while before the career of the oldest among us. So that it has all been built up in our very life-time. Before that but few of the functions of the animal economy could be understood. Physiology could make but little progress until the development of the fundamental science of chemistry.

The new theory of evolution has done much by informing us how our growth and development has been affected by our surroundings, and the young science of biology has conferred a great benefit by showing how diseases are occasioned by organisms which prey upon living beings, as well as the conditions favoring the attacks of these predatory parasites, and also the necessity, as well as the means, of destroying them. It also has shown us how nature attempts to preserve the health and life of both animals and plants by excreting the products of parasitic life, and also by providing ingredients poisonous to the parasites. In this way plants furnish us with some of our most valuable germicides, and a careful and extended study of them may furnish us with other, and, may be, still more valuable and destructive means than any we now possess. Though quinine is the most valuable antidote we yet know of, for the malarial poison, that it is the only one or the most efficacious one to be found in nature, is preposterous, or that it is the only germicide equally powerful in all zymotic diseases is unphilosophical in the extreme.

We have reached the point now where it has become necessary to study the minute differences between germicides to ascertain precisely which are most efficacious in the various diseases of parasitic origin. Thus by the germ-theory of disease, the whole treatment of zymotic diseases has been revolutionized.

Before these recent discoveries we unconsciously made use of some germicides without knowing how they proved efficacious. Mercury had long been used for the destruction of epizoæ, but when we administered it internally, it was never supposed that it was for the purpose of destroying entozoæ. We can *now* understand its power in the suppurative processes. The use of this valuable agent was one of those stumblings on the truth, of which we have many examples. In selecting our germicides we are furnished with a key by Mr. Law, which, as far as is known, he was the first to enunciate on this floor, viz., that "no organism can live in its own excreta, that the products of its life-processes become poisonous to it, stop its ravages and destroy its life." If this be true, we have only to saturate it with its own exhalations. We know how efficacious this is when carbonic acid is the exhalation; when it is alcohol; when it is ammonia, as in typhoid fever; when it is sulphuretted hydrogen, as in some cases of indigestion. The examples might be multiplied indefinitely.

He announced it as his belief that it is only as a germicide, an antidote, that we use quinine, without any reference to its therapeutical or physiological powers; that these, about which there is such difference of opinion, are ignored and disregarded, and we use it in any condition of the system in spite of them.

The time devoted to the zymotic phase of the subject prevented an extended notice of the treatment of diseases due to a chemical fault, the results of which are as certain as chemical reactions themselves. He considered that a great advance had been made by Koch's discovery of the bacillus tuberculosis, notwithstanding the efforts of Dr. H. F. Formad, of the University of Pennsylvania, to disparage them. We have many formations analogous to the tubercle among animals as well as among plants of undoubted parasitic origin, which renders it highly probable that this abnormal formation is due to a like cause.

We already begin to see results from these advances, in the interest manifested in sanitary science, in State medicine, in the establishment of health boards, in the stamping out of epidemics, or in depriving them of their virulence, in the lessening of disease, and, finally, in diminishing death-rate.

Though some striking figures could be furnished from private practice to substantiate these assertions, for fear of a misinterpretation of motive they will not be produced, but only those furnished by the army and navy will be made use of for this purpose.

In the army the numbers on the sick-list diminished from 18.63 to the thousand of mean strength in the year 1871, to 15.13 in the year 1881 (white troops). In the whole army, both white and colored, from 18.04 in the year 1871, to 15.36 in the year 1881.

The number of deaths from disease, per thousand cases treated, declined from 6.78 in 1871, and 7.22 in 1872, to 4.32 in 1881, being as low as 3.75 and 3.97 (colored) in 1877.

The number of deaths per thousand of mean strength declined from 12.13 in 1871 to 6.64 in 1881, about one-half. Though the navy reports do not show such a decline in the number of cases treated, they show equally as favorable results in the cases actually treated.

In the year	1875	there were	627	cases treated	to 1000	men
"	1876	"	561	"	"	"
"	1877	"	687	"	"	"
"	1878	"	702	"	"	"
"	1879	no report				
"	1880	there were	990.87	"	"	"

In the year	1875	there were	3.84	deaths	to 1000	men
"	1876	"	2.51	"	"	"
"	1877	"	2.35	"	"	"
"	1878	"	4.61	"	"	"
"	1880	"	2.94	"	"	"

Deaths to the one thousand cases treated declined from 6.11 in 1875, to 2.74 in 1880.

The city of Norfolk furnishes further proof of the value of medical practice, by the diminution of the death-rate after the restoration of an appropriation for medicines for the poor, which had been withdrawn for three years, which, as a consequence, were three years of very heavy mortality. During those three years the work of the irregular practitioners was very much increased, as they supplied their own medicines. Their losses were enormous, notably in cholera infantum and diphtheria.

We conclude, then, that we are not spending our energies on the baseless fabric of a vision, that we are not imposing upon the public a myth, the product of a distempered brain, but that the noble art to which we are devoting our time, our talents, and our energies, is the outcome of a sound philosophy built upon sciences, the principles of which have been evolved by the highest modern cultivated intellects.

Afternoon Session.

Dr. Wm. D. Cooper, of Morrisville, Va., the retiring president, was duly elected an

HONORARY FELLOW OF THE SOCIETY.

Dr. Wm. C. Dabney, of Charlottesville, Va., read a paper entitled

THE PRESENT ASPECT OF THE BACILLUS TUBERCULOSIS QUESTION.

He reminded his hearers that bacilli have been found in many other places than in tuberculous cavities. His conclusions may be summarized as follows:

1. The bacilli observed by Koch in the sputa and

tissues of tubercular patients, and considered by him the essential cause of tuberculosis, are not peculiar to this disease, but are found in a number of other diseased conditions, and even in some of the discharges of healthy persons.

2. It is probable that they make their appearance in the caseous masses subsequent to their formation, these masses furnishing a suitable soil for their growth and multiplication.

3. Experiments made with "indifferent substances," and the still stronger evidence furnished by the experience at the Brompton Hospital, render it highly probable that the bacilli are not the primary and essential cause of the disease.

4. The inoculation-experiments of Koch are not conclusive, because they were made chiefly on animals in which any irritant is liable to set up a caseous inflammation, the caseous matter thus formed furnishing a suitable nidus for the development and growth of bacilli, and being capable of producing tuberculosis by inoculation (whether owing to the presence of bacilli or not is unknown as yet).

5. It is probable that the presence of the bacilli in the lungs, or rather, diseased organs, may hasten the advance of the morbid process.

DR. CHAS. M. SHIELDS, of Richmond, then presented his report on the

ADVANCES IN OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY,

of which the following is an abstract.

The relation of diseases of the general system to some forms of eye trouble was first considered, mention being made of the several forms of choroidal trouble due to uterine disease; of malarial hemeralopia, and the effects of pernicious anæmia on the retina. In the progress of the physiology and anatomy of the eye, the amount of albumen in the aqueous was stated to be .03; and attention called to the discovery by Giacomini of cartilage in the semilunar folds of the negro, and its absence in the white race. In connection with the subject of *sympathetic ophthalmia*, he alluded to the investigations of Krause, who found that in eyes in which neurotomy had been performed, the cornea again became sensitive, and the ciliary nerves reunited; from which he drew the conclusion that unless patients could be kept under occasional observation, enucleation should be performed instead of neurotomy, when circumstances called for one or the other.

Trituration of the cortex of the lens, to hasten the development of cataract, was found successful by Förster, of Europe, and Mettendorf and others of this country, it being performed by kneading the lens by pressure on the cornea with a cataract-spoon after an iridectomy, and while the anterior chamber was empty. The recently suggested use of eserine in iritis was favorably commented on, *i. e.*, to employ it to reduce the vascularity of the iris, while mydriasis was still kept up with atropine. He favored its use, too, in episcleritis. The method of M. Badal of stretching the external nasal nerve in the treatment of glaucoma was mentioned, as was eserine also, but the advice was given of keeping the patient under observation after the use of either, and to resort to iridectomy at first if the patient could not be occasionally seen. Eserine has proved useful in hemeralopia, peripheral ulceration of the cornea, and hydrophthalmus. The use of the *electro-magnet* in removing foreign bodies from the vitreous and lens was referred to, and the employment of galvano-puncture in detachment of the retina. *Jequirity* has been found useful in granular lids, in the form of an infusion; 32 of the powdered seeds are added to 1000 grammes of water. The infusion, when painted on the lids, produces a mild form of purulent ophthalmia. On the healing of this, the granulations are usually found to be cured. He exhibited some samples of this agent. *Hydrobromate of homatropine* was advised for dilating the pupil for ophthalmoscopic purposes, its effects lasting for a shorter time than any of the other mydriatics. Nitrite of amyl in quinine amaurosis, boracic acid in granular lids, and iodoform in croupous conjunctivitis were mentioned.

Taking up *Otology and Laryngology* he referred favorably to the use of sulphide of calcium in otitis externa and furuncles of the meatus, also in mastoid disease. A *résumé* of an interesting report by Dr. E. Weil, of Stuttgardt, showed a much larger percentage of school-children affected with ear disease than was generally supposed to be the case. Speaking of the methods of removing foreign bodies from the ear, he said that over eighty per cent. could be removed with the syringe, and if swollen, the addition of alcohol would cause them to contract. If the syringe fails, then the blunt hook or forceps are to be used under good illumination. A case of transient poisoning from the instillation of a solution of atropine in a healthy ear for ear-ache was reported. The "dry method" of treating otorrhœa was considered and mention was made of the use of the finger in the diagnosis of post-nasal disease. In post-nasal and nasal catarrh he advocated the use of insufflations of nitrate of silver and calcined magnesia, as suggested by Schalle; the proportions 1 to 15, 1 to 10, and 1 to 6 being the most useful. Most cases of catarrh are benefited by using purified lamb's wool in the nostrils to prevent cold air, dust, etc., from coming in contact with the diseased surfaces. In hypertrophic nasal catarrh, he considered nearly all treatment unavailing, unless the thickened tissue is removed with Jarvis' snare or the galvano-cautery.

(*To be concluded.*)

CANADA MEDICAL ASSOCIATION.

Sixteenth Annual Meeting, held at Kingston, Ontario, September 5, 6, and 7, 1883.

(Specially reported for THE MEDICAL NEWS.)

KINGSTON, the old capital of Canada, offers certain advantages for the meeting of a medical association. Though a town of only sixteen thousand inhabitants, the profession comprises men of considerable energy and ability. For thirty years it has been the seat of a medical school—the Royal College of Physicians and Surgeons—which is in affiliation with Queen's University. There are two hospitals: the general, a Protestant, and the Hôtel Dieu, a Catholic institution. The Provincial penitentiary is situated here, and has about six hundred inmates, and there is a large asylum for the insane, with five hundred patients. Queen's University, the Presbyterian college of Canada, is a well-endowed institution, with about two hundred students. The Military College of Canada is also here. Situated at the east end of Lake Ontario, close to the Thousand Islands, the city is unusually well placed for excursions, etc.

SEPTEMBER 5TH, FIRST DAY.—MORNING SESSION.

GENERAL MEETING.

The meeting was called to order by the PRESIDENT, DR. JOHN MULLIN, of Hamilton, Ont., and the Association was warmly welcomed by the Mayor on behalf of the citizens, and by Dr. Sullivan on behalf of the profession.

Dr. Hunt, of the Asylum for the Insane at Pontiac, Mich., Prof. McLean, of Ann Arbor, Mich., Dr. Walker, of Detroit, delegate from the American Medical Association, and Dr. Dorland, of Milwaukee, delegate from the Wisconsin State Medical Society, were invited to the platform.

After the reading of minutes and election of members, the reports of committees were then taken up.

Dr. Canniff, of Toronto, as Chairman of the

SPECIAL COMMITTEE ON VITAL STATISTICS,

reported that the committee had never held any meeting, and that he had been frustrated in his efforts to secure a grant from the Dominion Government for the collection of vital statistics. He read letters showing that this had been caused by Dr. Larocque, Dr. Playter, and others calling a convention at Ottawa and forming a separate society, for which they succeeded in getting a grant from the Government.

Drs. Playter and **Larocque** explained their connection with the convention referred to, and showed that the matter was entirely an oversight. They were under the impression that the special committee of which Dr. Canniff was president had ceased to exist after last year's meeting.

Dr. Larocque, of Montreal, read a most exhaustive report from the

COMMITTEE ON CLIMATOLOGY AND PUBLIC HEALTH,

which was received.

Dr. Oldright noted two or three points which he thought should be discussed. The first of these was the subject of local boards of health. He thought the efforts of the Association should be used to have these established in all parts of the Dominion by the various Provincial governments. Other important subjects were the reporting of contagious diseases to the authorities and the licensing of plumbers. He thought, also, that the removal of sanitary legislation from the Provincial to the Federal government, as recommended by the report, would be a mistake. There was sufficient work for both. The Dominion government should attend to such subjects as adulteration of food, immigration, and commerce and manufactures.

Dr. Yeomans remarked that a systematic report of contagious diseases was furnished to all the schools of Hamilton, by means of which the mortality among the school-children had been reduced and the attendance at the schools increased.

A vote of thanks was tendered to Dr. Larocque for his able report.

Drs. Botsford, G. E. Fenwick, Grant, Graham, Rogers, Bray, Worthington, Malloch, Gliver, Eye, Sweetland, Canniff, Oldwright, and the President were appointed a

SPECIAL COMMITTEE ON NOMINATIONS.

Dr. Metcalf extended an invitation to the membeers to make a

VISIT TO THE ASYLUM

at their convenience, after which the meeting adjourned to meet at 2 P. M.

Afternoon Session.

The afternoon session opened at 2.30, and the first business was

THE PRESIDENT'S ADDRESS,

in which **Dr. Mullin** briefly returned thanks for the honor which had been conferred upon him, and then referred to the presence of both old and young physicians. They were both welcome, especially the former, whose attendance showed that their eyes were not dim, nor their natural forces abated. A brief allusion was made to the death of Dr. David, of Montreal, late Secretary of the Association. It had been remarked that the itinerancy of the Association had been opposed to its usefulness and jeopardized its existence, yet every meeting gave increased confidence in its success. All who attended its sessions recognized the advantages derived from every place where it had met. Each had given its special contribution to the success of the Association, and in each place it had elicited the cordial support of the profession. We look for continued success when we reflect on the standing of the profession in this vicinity, and remember that we have come to an important centre of education and culture. Every member of this Association gladly recognizes that the institutions of this city remain worthy of the history of Eastern Ontario, and exercise their influence over the youth of the present with increased vigor, corresponding to the growth of our country. He said that the importance of the annual meeting could not be over-estimated. Each of the medical societies had its spheres of usefulness; the country, city, and provincial associations could do work that would advance the interest and knowledge of the members of the profession, but the highest and best results may be attained by the Association gathering to it each year the members of the profession from all parts of the Dominion, who in the discussions would reflect the progress they were able to make. All cordially agreed with the remarks made by the president of the Ontario Medical Association at its late meeting, who referred to the relationship of the various local societies to the Dominion Association, and indicated that while each worked in its own sphere, all should coöperate and endeavor to promote the work of the Dominion Association. The speaker said he would not attempt even a slight sketch of the work of the past year, but would confine himself to one subject—the agencies through which the decomposition of organic substance was effected. As practitioners of medicine all must recognize that while chemical affinities might and do play their part, the decompositions referred to were attended with and seemed to be dependent upon the growth and development of vegetable forms. He referred to the several experiments that had been made in support of this theory. He concluded by saying: "Our knowledge at present is in accordance with that long since found true, that as regards contagious fevers and tubercular diseases our efforts must depend to a great extent on our success in teaching the public to rely less upon antidotes and more upon those means which tend to build up strong frames capable of withstanding the agencies causing disease; that our main hope of lessening the mortality from these diseases lies in the carrying out by the public of proper sanitary measures, and, as regards the individual, attention to the laws of health."

Medical Section.

Dr. Graham, of Toronto, in the chair.

DIET AS A THERAPEUTIC AGENT.

Dr. Playter, of Toronto, urged the necessity and importance of proper diet in acute and chronic maladies, and spoke of the ailments induced by the habitual consumption of an excess of food.

In the remarks which followed, **Dr. Reeve**, of Toronto, stated that he believed that many cases of phlyctenular ophthalmia in children were caused by over-eating of fresh fruit. He had known instances in which fruit had been given in considerable amount to sucklings.

Dr. Graham referred to the important influence of food in skin affections; many acute attacks depend upon peculiar sorts of food, while many chronic maladies may be produced by either a defective or excessive diet.

INVAGINATED AND GANGRENOUS BOWEL.

DR. SHEARD, of Toronto, presented the specimen, and read notes of the case. The specimen showed eight or nine inches of the ileum invaginated in the colon and gangrenous. The patient, a man, aged thirty-seven, had a right inguinal hernia, which became strangulated, and was reduced, but without the cessation of the prominent symptoms. A tumor appeared in the right iliac region, and Dr. Burns opened the abdomen, when the condition above described was discovered. The hernia was omental, and apparently had had nothing to do with the intussusception. The man died shortly after the operation.

INFLATION OF THE LUNGS BY ABDOMINAL AND THORACIC TRACTION.

DR. BOTSFORD, of St. Johns, N. B., described the method which he believed might be of some service in cases of suspended breathing in drowning, during anæsthesia, or in new-born children. By means of pieces of plaster, four by four inches, fitted with rubber rings, and applied on the abdomen or lower thorax, traction could be made in such a way as to draw down the diaphragm. The doctor had not had an opportunity of trying his method, but he thought the suggestion might be of some value.

DR. BURNHAM, of Toronto, late House Surgeon at the Royal London Ophthalmic Hospital, stated that in that institution they had had no deaths from anæsthetics for six or seven years, though, of course, among the very large number anæsthetized every year many cases occurred in which methods of resuscitation had to be employed. In a case of danger one assistant straddled the patient and exerted pressure on the abdomen, while a second performed artificial respiration with the arms. Inhalation of amyl nitrite was employed, and believed to be of the greatest value.

SUCCESSIVE DROPSIES OF THE AMNION, ALWAYS SPECIFIC.

DR. DORLAND, of Milwaukee, Wis., presented the report of six cases in which, in successive pregnancies, the amount of liquor amnii was in great excess, and in all evidence of syphilis could be obtained. In several of the cases specific treatment seemed to be successful in preventing the condition, which had occurred in previous pregnancies. The cases were given in detail, and the doctor had had the patients under observation for some years, all of them having occurred in family practice.

In the discussion which followed, Dr. Mullin narrated a case in which, with a syphilitic child, the amount of liquor amnii was very large. Dr. Yeomans and others mentioned instances in which there was no suspicion of syphilis.

MEDICAL ETHICS.

DR. DUPIUS, of Kingston, read a paper on the *Relation of Medical Men to Each Other, and to Each Others Patients*, which was largely a plea for free trade in medicine.

Dr. Harrison, of Selkirk, Dr. Canniff, of Toronto, and Drs. McCannon and Oliver, of Kingston, repudiated warmly the opinions expressed by Dr. Dupius, and there appeared to be a very general feeling that a mistake had been made in permitting such a communication to come before the Society.

HYOSCYAMINE IN THE TREATMENT OF MENTAL DISEASES.

The results of six years' experience with the drug were given by DR. METCALF, of the Kingston Asylum. Of the two preparations of Merck, the crystalline was preferred. The dose given was from one-twelfth to one-eighth of a grain, hypodermically. Two great advantages were promptitude and certainty. In sixty patients treated in all forms, no ill-effects had followed, and very many were benefited. One full dose was usually given daily; if after a few doses no benefit followed, the use of the drug was discontinued. In some forms recovery appeared to follow; six cases of severe mania were all benefited, and it seemed advantageous in all forms of maniacal excitement.

DR. HURD, of Pontiac, Mich., had little to add to Dr. Metcalf's experience. The drug appeared to change the mental action. Intoxication may be produced. He had found particular benefit in cases of melancholia with persistent refusal of food. It appeared to change the delusion on which the refusal depends. In these cases he gave small doses of one-twenty-fourth to one-forty-eighth of a grain. In one patient choreiform movements appeared, ceased with the interruption of the medicine, and reappeared when again administered. It seemed to increase the appetite, and the patients often awoke hungry. It should never be given in large doses where there is any fatty degeneration of the heart.

DR. DANIEL CLARKE, of the Toronto Asylum, thought that the drug should be more widely used by general practitioners in cases of delirium tremens, acute mania, and melancholia with suicidal tendency. He used Merck's preparation, and also the tincture (B. P.), not in the ordinary doses, but as much as one and a half ounces. He had found the greatest benefit in sthenic mania, and if it is to do good, two or three doses will suffice.

DR. THORBURN, of Toronto, suggested caution in the use of such doses of the tincture as recommended by Dr. Clarke. He had a lively remembrance of the introduction by Jones, of Jersey, of large doses of digitalis in delirium tremens. He gave two instances in which a fatal result had apparently been caused by large doses of this medicine.

DR. TROUTMAN, of New York, had had much experience, and placed great reliance on the drug. It is contra-indicated in acute delirium with dryness of tongue and muscular tremors. It is also injurious in general paresis with much excitement.

LEPROSY IN NEW BRUNSWICK.

DR. GRAHAM, of Toronto, read an exhaustive paper based on a study of the leper settlement at Tracadie, N. B. The region in which the disease appears has about two thousand inhabitants, chiefly French-Canadians, who live on small farms, and also engage in fishing and hunting. The diet is mainly fish, potatoes, and bread, with but little meat. They are partial to stale fish, preferring it to fresh. Large families live in small rooms. He had made a thorough investigation into the family history of the various sufferers, and presented interesting genealogical charts. At present there are only twenty-four patients in the Lazaretto, and the average length of residence is five years. A few cases are at large, and it is chiefly through the influence of the priests that they are detected and secluded. Dr. Graham's conclusions are as follows:

1. Although it has been shown in other countries that the disease can be propagated purely by hereditary influences, no case has yet been recorded in Tracadie, so far as he could learn, which would prove that theory.

2. That the disease was imported from without, and, finding favorable surroundings, it spread from one to another by contagion. In order to contract the disease, certain conditions appear necessary: (*a*) low state of the system. It has been noticed in Tracadie that persons die from very slight ailments and that there is very little power of resisting disease. (*b*) To belong to certain race or family. The Le Bretons

among the Tracadie families entirely escaped. (*c*) Lengthened and intimate contact with leprous persons with frequent opportunities for inoculation.

Surgical Section.

Dr. Tye, of Chatham, Ont., in the Chair.

IMPERFORATE ANUS WITH FECAL FISTULA.

Dr. Fenwick, of Montreal, narrated the case, which was that of a man admitted to the General Hospital with a remarkable malformation of the lower bowel. There was a small opening at the site of the anus, and another at the root of the penis, just in front of the scrotum. The orifice in the perineum was the result of an operation for imperforate anus shortly after birth. The canal in the perineum leading from the rectum appeared like a direct continuation of the bowel. The case was a very unusual one, and it was decided to close the perineal canal, which was done without much difficulty. Prof. McLean, Drs. Walker, Holmes, and Bethune took part in the discussion.

RETROVERSION AND RETROFLEXION OF THE UTERUS.

Dr. Worthington, of Clinton, read a paper on four interesting cases. A prolonged discussion followed on the best modes of treatment, Drs. Gardner, Holmes, Tye, Fulton, and Hingston taking part.

FEMORAL HERNIA.

Dr. Campbell, of Seaforth, Ont., read the notes of a case of femoral hernia in which he had operated successfully after three and a half days' duration of the symptoms.

PARACENTESIS PERICARDII.

Dr. McDonald, of Londonderry, N. B., reported a case in which over twenty ounces of pus were removed from the pericardium and recovery took place.

EXPERIMENTS ON RESECTION OF THE BOWEL.

Dr. James Bell, of the General Hospital, Montreal, gave the results of a series of experiments in which he had removed portions of the bowel in dogs, the length of the pieces ranging from a few inches to a foot and a half or two feet. In almost every instance the animal recovered perfectly, and when killed at a later period perfect union was found with no narrowing of the calibre of the gut. A series of specimens illustrating the experiments was shown, and the paper concluded with a description of cases which the writer had observed in which abdominal section and removal of portion of the bowel would have been justifiable.

Thursday, September 6th, Second Day.

Morning Session.

General Meeting, 10 a.m.

After the reading of the minutes, Dr. Fulton, of Toronto, read the

REPORT OF THE COMMITTEE ON NECROLOGY,

and gave a list of thirty-seven members of the profession who had died since the meeting in Toronto last year.

Dr. Thorburn, of Toronto, presented the

REPORT ON EDUCATION,

and referred more particularly to the establishment of schools of medicine for women in Toronto and Kingston. He congratulated the Province of New Brunswick on the steps which had been taken to advance the standard of education in that province by establishing a Medical Council and an Examining Board.

After the election of new members, the Association adjourned to the sections.

The President announced that those gentlemen interested in sanitary matters would meet and organize a

PUBLIC HEALTH SECTION,

in order to consider the best ways of furthering the establishment of the proposed sanitary association.

Medical Section.

Dr. Graham, in the chair.

PIGMENTARY DEGENERATION OF THE RETINA.

Dr. Tobin, of Halifax, N. S., gave an interesting case of four deaf-mutes in one family, all of whom presented characteristic symmetrical changes in the eyes in the form of scattered pigment masses on the retinæ, often in stellate forms. The parents were cousins. A full account of the disease was given, and the cases supported the views of Liebreich and De Wecker, who believe that a considerable proportion of them occur as the result of consanguineous marriages. A fifth case was also described.

Dr. Butler, of Montreal, had seen very many instances of the kind, and had never succeeded in tracing any connection between consanguinity and pigmentary degeneration; nor had he been more fortunate in trying to associate, as done by some writers, these cases with hereditary syphilis.

GENERAL HYDRARTHROSIS OF THE SMALLER JOINTS.

Dr. Fife Fowler, of Kingston, showed a child with enlargement of the smaller joints, wrists, ankles, and phalanges, due apparently to effusion. There had been enlargement of the spleen and the child had been out of sorts for many months.

DR. MORTIMER GRANVILLE'S PERCUTEUR.
